

Traffic Management Specification Version 4.1

AF-TM-0121.000

March 1999

© 1999 by The ATM Forum. This specification/document may be reproduced and distributed in whole, but (except as provided in the next sentence) not in part, for internal and informational use only and not for commercial distribution. Notwithstanding the foregoing sentence, any protocol implementation conformance statements (PICS) or implementation conformance statements (ICS) contained in this specification/document may be separately reproduced and distributed provided that it is reproduced and distributed in whole, but not in part, for uses other than commercial distribution. All other rights reserved. Except as expressly stated in this notice, no part of this specification/document may be reproduced or transmitted in any form or by any means, or stored in any information storage and retrieval system, without the prior written permission of The ATM Forum.

The information in this publication is believed to be accurate as of its publication date. Such information is subject to change without notice and The ATM Forum is not responsible for any errors. The ATM Forum does not assume any responsibility to update or correct any information in this publication. Notwithstanding anything to the contrary, neither The ATM Forum nor the publisher make any representation or warranty, expressed or implied, concerning the completeness, accuracy, or applicability of any information contained in this publication. No liability of any kind shall be assumed by The ATM Forum or the publisher as a result of reliance upon any information contained in this publication.

The receipt or any use of this document or its contents does not in any way create by implication or otherwise:

- Any express or implied license or right to or under any ATM Forum member company's patent, copyright, trademark or trade secret rights which are or may be associated with the ideas, techniques, concepts or expressions contained herein; nor
- Any warranty or representation that any ATM Forum member companies will announce any product(s) and/or service(s) related thereto, or if such announcements are made, that such announced product(s) and/or service(s) embody any or all of the ideas, technologies, or concepts contained herein; nor
- Any form of relationship between any ATM Forum member companies and the recipient or user of this
 document.

Implementation or use of specific ATM standards or recommendations and ATM Forum specifications will be voluntary, and no company shall agree or be obliged to implement them by virtue of participation in The ATM Forum.

The ATM Forum is a non-profit international organization accelerating industry cooperation on ATM technology. The ATM Forum does not, expressly or otherwise, endorse or promote any specific products or services.

NOTE: The user's attention is called to the possibility that implementation of the ATM interoperability specification contained herein may require use of an invention covered by patent rights held by ATM Forum Member companies or others. By publication of this ATM interoperability specification, no position is taken by The ATM Forum with respect to validity of any patent claims or of any patent rights related thereto or the ability to obtain the license to use such rights. ATM Forum Member companies agree to grant licenses under the relevant patents they own on reasonable and nondiscriminatory terms and conditions to applicants desiring to obtain such a license. Tel: +1-650-949-6700 Fax:+1-650-949-6705 This specification consolidates the dedication and creativity of many individuals. This work would not have been possible without the involvement of the numerous members of The ATM Forum Traffic Management Working Group who made contributions to enhance, analyze, challenge, discuss, and review the specification.

The following individuals deserve mention for their involvement in the production of this specification:

- John Kenney, Editor, Traffic Management Working Group
- Vijay Samalam, former Vice-chair, Traffic Management Working Group

This specification also includes previous Traffic Management concepts which were specified as part of UNI 3.1 and TM 4.0. Special thanks are extended to the following people for producing these parts of the specification:

- Shirish Sathaye, former Editor, Traffic Management Working Group
- Jim Ormord, former Vice-chair, Traffic Management Working Group
- Dave McDysan, former Chair, Traffic Management Working Group
- Lou Wojnaroski, former Editor, Traffic Management Working Group

Natalie Giroux, Chair The ATM Forum Traffic Management Working Group

Preface

This is Version 4.1 of the ATM Forum Traffic Management Specification. It replaces Traffic Management Specification Version 4.0 (af-tm-0056.000, April 1996) and Addendum to Traffic Management V4.0 for ABR parameter negotiation (af-tm-077.000, January 1997). The previous versions of the traffic management specification may be found in:

- Traffic Management Specification Version 4.0, af-tm-0056.000, April 1996, available at: ftp://ftp.atmforum.com/pub/approved-specs/af-tm-0056.000.pdf
- ATM User-Network Interface (UNI) Specification Version 3.1, September 1994, Prentice Hall PTR, Upper Saddle, NJ 07458, ISBN 0-13-3933828-X.

This document uses the following two levels for indicating the degree of compliance necessary for specific functions/procedures/coding associated with traffic management:

- Requirement (R): functions, procedures, and coding necessary for operational compatibility.
- Option (O): functions, procedures, and coding that may be useful, but are not necessary for operational compatibility.

When a level is not specified, the level "**Requirement** (**R**)" should be assumed to hold. In this specification, annexes are normative and appendices are informative.

The major advance of this version is:

 Definition of the GFR service category (See especially Sections 2.5 and 4.5.5, Annex B.5, and Appendix VI)

Other additions to this version include:

- Clarifications to the Usage Parameter Control (See Section 5.3)
- Clarification of the operation of ABR VPCs (See Section 5.10.9)
- Clarification of VCC to VPC multiplexing effects (See Appendix V)
- Additional examples on ABR implementations (See Appendix I.5)

1. Introduction

ATM technology is intended to support a wide variety of services and applications. The control of ATM network traffic is fundamentally related to the ability of the network to provide appropriately differentiated Quality of Service (QoS) for network applications. This specification defines procedures and parameters related to Traffic Management and Quality of Service. A primary role of traffic management is to protect the network and the end-system from congestion in order to achieve network performance objectives. An additional role is to promote the efficient use of network resources.

A set of six service categories are specified. For each one, a set of parameters is given to describe both the traffic presented to the network, and the Quality of Service (QoS) which is required of the network. A number of traffic control mechanisms are defined, which the network may utilize to meet the QoS objectives.

1.1 Generic Functions

To meet these objectives, the following functions form a framework for managing and controlling traffic and congestion in ATM networks and may be used in appropriate combinations depending on the service category.

- Connection Admission Control (CAC) is defined as the set of actions taken by the network during the call set-up phase in order to determine whether a connection request can be accepted or should be rejected (or whether a request for re-allocation can be accommodated).
- Feedback controls are defined as the set of actions taken by the network and by end-systems to regulate the traffic submitted on ATM connections according to the state of network elements. This specification defines one network feedback control mechanism: the ABR flow control. The ABR flow control may be used to adaptively share the available bandwidth among participating users.
- Usage Parameter Control (UPC) is defined as the set of actions taken by the network to monitor
 traffic and enforce the traffic contract at the User Network. Network Parameter Control (NPC) is a
 similarly defined set of actions at the Network Node Interface. The main purpose of UPC and NPC
 is to protect network resources from malicious as well as unintentional misbehavior, which can affect
 the QoS of other already established connections, by detecting violations of negotiated parameters
 and taking appropriate actions. Such actions may include cell discard and cell tagging.
- Cell Loss Priority control: For some service categories the end system may generate traffic flows of
 cells with Cell Loss Priority (CLP) marking. The network may follow models which treat this
 marking as transparent or as significant. If treated as significant, the network may selectively discard
 cells marked with a low priority to protect, as far as possible, the QoS objectives of cells with high
 priority.
- Traffic Shaping: Traffic shaping mechanisms may be used to achieve a desired modification to the
 traffic characteristics of a connection. The objectives of this function are to achieve a better network
 efficiency whilst meeting the QoS objectives and/or to ensure connection traffic conformance at a
 subsequent interface.
- Network Resource Management: The service architecture allows logical separation of connections
 according to service characteristics. Although cell scheduling and resource provisioning are
 implementation and network specific, they can be utilized to provide appropriate isolation and access
 to resources. Virtual Paths are a useful tool for resource management.
- Frame Discard: A congested network that needs to discard cells may discard at the frame level rather than at the cell level. The definition of a frame, and the concept of frame discard are discussed in Section 5.8.

1.2 Relation with Other Documents

This specification expands on some topics in ITU-T Recommendations I.371, I.356, and I.150. Section 4 of this specification is closely related to ITU-T Recommendation I.371. Some differences are as follows:

- The service categories of the ATM Forum are called ATM transfer capabilities in I.371. Some of the ATM service categories of the ATM Forum are equivalent to some of the ATM transfer capabilities in I.371 but have different names: Constant Bit Rate (CBR) is called Deterministic Bit Rate (DBR) in I.371 and Variable Bit Rate (VBR) is called Statistical Bit Rate (SBR) in I.371. In general, a mapping between the ATM Forum service categories and the ATM transfer capabilities can be made with the following discrepancies:
 - The ATM Forum distinguishes between real-time VBR.1, VBR.2, VBR.3 and non-real-time VBR.1, VBR.2, VBR.3, while I.371 specifies non-real-time SBR.1, SBR.2, SBR.3 and real-time SBR.1. See Table VII-2.
 - The ATM Forum has a service category Unspecified Bit Rate (UBR) which has no equivalent ATM transfer capability in I.371.
 - I.371 partially specifies an ATM transfer capability, ATM Block Transfer (ABT), which has no equivalent in this specification.
 - ABR is fully specified in this specification, but the ABR transfer capability is only partially specified in I.371 and is still under study.
 - The ATM Forum defines the GFR service category. The GFR ATC is under study in ITU-T.
- Differences from ITU-T Recommendation I.356 include:
 - This specification provides for negotiation of the following QoS parameters on a connection basis:
 - Peak-to-peak Cell Delay Variation,
 - Maximum Cell Transfer Delay
 - Cell Loss Ratio
 - ITU-T Recommendation I.356 only defines QoS classes. However, in this specification, individual QoS parameters are specified and QoS classes are retained for backward compatibility.

Note: ITU-T Study Group 13 intends to include a single end-to-end objective applicable for all connections for CER, SECBR, and CMR, in ITU-T Recommendation I.356.

- Differences exist in the use of RM-cell fields QL and SN defined in ITU-T Recommendation I.371, and the source, destination and switch behaviors (not yet specified in ITU-T Recommendation I.371).
- ITU-T Recommendation I.371 (Section 6.2.3) states that "The use of a UPC function is recommended, and the use of an NPC function is a network option." In this specification, the UPC is optional.

2. ATM Service Architecture

The architecture for services provided at the ATM layer consists of the following six service categories:

- **CBR** Constant Bit Rate
- **rt-VBR** Real-Time Variable Bit Rate
- nrt-VBR Non-Real-Time Variable Bit Rate
- **UBR** Unspecified Bit Rate
- **ABR** Available Bit Rate
- GFR Guaranteed Frame Rate

These service categories relate traffic characteristics and QoS requirements to network behavior. Functions such as routing, CAC, and resource allocation are, in general, structured differently for each service category. Service categories are distinguished as being either real-time or non-real-time. For real-time traffic, there are two categories, CBR and rt-VBR, distinguished by whether the traffic descriptor contains only the Peak Cell Rate (PCR) or both PCR and the Sustainable Cell Rate (SCR) parameters. The four non-real-time categories (nrt-VBR, UBR, ABR, and GFR) are compared and distinguished in some detail in Section 2.3. All service categories, except GFR, apply to both VCCs and VPCs. GFR is a frame-aware service that only applies to VCCs since frame delineation is not usually visible at the virtual path level. Throughout this document, the term "connection" refers to either VCCs or VPCs unless otherwise stated.

The specification of a real-time service category that uses a feedback flow control mechanism similar or identical to that used for ABR is for further study.

This specification uses Resource Management cells, (RM-cells) to control the cell flow of ABR connections. The use of RM-cells for the control of CBR, rt-VBR, nrt-VBR or UBR or GFR connections is not defined in this specification. However, RM-cells are allowed on such connections. If RM-cells are present on such connections, then they are considered as part of the user data cell flow.

Informative Appendix IV illustrates this service architecture by discussing how different applications may map into each service category.

2.1 Definitions for Service Categories

This section defines the ATM service categories using the following QoS parameters. These QoS parameters are defined in Section 3.6.

- Peak-to-peak Cell Delay Variation (peak-to-peak CDV)
- Maximum Cell Transfer Delay (maxCTD)
- Cell Loss Ratio (CLR)

Each of the following service categories will have one or more conformance definitions, as defined in Section 4.5. These Conformance Definitions are distinguished by the manner in which the QoS parameters, particularly CLR, apply to the CLP=0 or CLP=0+1 cell flows.

2.1.1 Constant Bit Rate (CBR) Service Category Definition

The Constant Bit Rate service category is used by connections that request a static amount of bandwidth that is continuously available during the connection lifetime. This amount of bandwidth is characterized by a Peak Cell Rate (PCR) value.

The basic commitment made by the network to a user who reserves resources via the CBR capability is that once the connection is established, the negotiated ATM layer QoS is assured to all cells when all cells are conforming to the relevant conformance tests. In the CBR capability, the source can emit cells at the Peak Cell Rate at any time and for any duration and the QoS commitments still pertain.

CBR service is intended to support real-time applications requiring tightly constrained delay variation (e.g., voice, video, circuit emulation) but is not restricted to these applications. In the CBR capability, the source may emit cells at, or below the negotiated Peak Cell Rate (and may also even be silent), for periods of time.

Cells which are delayed beyond the value specified by the maximum cell transfer delay (maxCTD) are assumed to be of significantly reduced value to the application.

2.1.2 Real-Time Variable Bit Rate (rt-VBR) Service Category Definition

The real-time VBR service category is intended for real-time applications, i.e., those requiring tightly constrained delay and delay variation, as would be appropriate for voice and video applications. rt-VBR connections are characterized in terms of a Peak Cell Rate (PCR), Sustainable Cell Rate (SCR), and Maximum Burst Size (MBS). Sources are expected to transmit at a rate that varies with time. Equivalently the source can be described as "bursty". Cells that are delayed beyond the value specified by maxCTD are assumed to be of significantly reduced value to the application. Real-time VBR service may support statistical multiplexing of real-time sources.

2.1.3 Non-Real-Time (nrt-VBR) Service Category Definition

The non-real-time VBR service category is intended for non-real-time applications which have bursty traffic characteristics and which are characterized in terms of a PCR, SCR, and MBS. For those cells which are transferred within the traffic contract, the application expects a low cell loss ratio. Non-real-time VBR service may support statistical multiplexing of connections. No delay bounds are associated with this service category.

2.1.4 Unspecified Bit Rate (UBR) Service Category Definition

The Unspecified Bit Rate (UBR) service category is intended for non-real-time applications, i.e., those not requiring tightly constrained delay and delay variation. Examples of such applications are traditional computer communications applications, such as file transfer and email.

UBR service does not specify traffic related service guarantees. No numerical commitments are made with respect to the CLR experienced by a UBR connection, or as to the CTD experienced by cells on the connection. A network may or may not apply PCR to the CAC and UPC functions. In the case where the network does not enforce PCR, the value of PCR is informational only. When PCR is not enforced it is still useful to have PCR negotiated, since this may allow the source to discover the smallest bandwidth limitation along the path of the connection. Congestion control for UBR may be performed at a higher layer on an end-to-end basis.

The UBR service is indicated by use of the Best Effort Indicator in the ATM User Cell Rate Information Element.

2.1.5 Available Bit Rate (ABR) Service Category Definition

ABR is an ATM layer service category for which the limiting ATM layer transfer characteristics provided by the network may change subsequent to connection establishment. A flow control mechanism is specified (Section 5.10) that supports several types of feedback to control the source rate in response to changing ATM layer transfer characteristics. This feedback is conveyed to the source through specific control cells called Resource Management Cells, or RM-cells. It is expected that an end-system that adapts its traffic in accordance with the feedback will experience a low cell loss ratio and obtain a fair share of the available bandwidth according to a network specific allocation policy. The ABR service does not require bounding the delay or the delay variation experienced by a given connection. ABR service is not intended to support real-time applications.

On the establishment of an ABR connection, the end-system shall specify to the network both a maximum required bandwidth and a minimum usable bandwidth. These shall be designated as peak cell rate (PCR), and the minimum cell rate (MCR), respectively. The MCR may be specified as zero. The bandwidth available from the network may vary, but shall not become less than MCR.

Further information on the ABR flow control model and service model can be found in Section 2.4.

2.1.6 Guaranteed Frame Rate (GFR) Service Category Definition

The GFR service category is intended to support non-real-time applications. It is designed for applications that may require a minimum rate guarantee and can benefit from accessing additional bandwidth dynamically available in the network. It does not require adherence to a flow control protocol. The service guarantee is based on AAL-5 PDUs (frames) and, under congestion conditions, the network attempts to discard complete PDUs instead of discarding cells without reference to frame boundaries. On the establishment of a GFR connection, the end-system specifies a PCR, and a Minimum Cell Rate (MCR) that is defined along with a Maximum Burst Size (MBS) and a Maximum Frame Size (MFS). The GFR traffic contract can be specified with an MCR of zero. The user may always send cells at a rate up to PCR, but the network only commits to carry cells in complete frames at MCR. Traffic beyond MCR will be delivered within the limits of available resources. There are no delay bounds associated with this service category. Further information on GFR can be found in section 2.5.

2.2 ATM Service Category Parameters and Attributes

Table 2-1 provides a list of ATM attributes (traffic parameters, QoS parameters, and feedback characteristics) and identifies whether and how these are supported for each service category. Traffic parameters are defined in Section 4 and Section 5. QoS parameters are defined in Section 3.

	ATM Layer Service Category					
Attribute	CBR	rt-VBR	nrt-VBR	UBR	ABR	GFR
Traffic Parameters ₄ :						
PCR and CDVT ₅	Specified		Specified 2	Specified 3	Specified	
SCR, MBS, CDVT ₅	n/a Specified		n/a			
MCR	n/a Specified					n/a
MCR, MBS, MFS, CDVT ₅	n/a					Specified
QoS Parameters ₄ :						
Peak-to-peak CDV	Specified			Unspecified		
MaxCTD	Specified			Unspecified		
CLR	Specified			Unspecified	See Note 1	See Note 7
Other Attributes:						
Feedback	Unspecified			Specified 6	Unspecified	

Table 2-1: ATM Service Category Attributes

Notes:

- 1. CLR is low for sources that adjust cell flow in response to control information. Whether a quantitative value for CLR is specified is network specific.
- 2. Might not be subject to CAC and UPC procedures.
- Represents the maximum rate at which the ABR source may ever send. The actual rate is subject to the control information.
- 4. These parameters are either explicitly or implicitly specified for PVCs or SVCs.
- 5. CDVT refers to the Cell Delay Variation Tolerance (see Section 4.4.1). CDVT is not signaled. In general, CDVT need not have a unique value for a connection. Different values may apply at each interface along the path of a connection.
- 6. See Section 2.4.

7. CLR is low for frames that are eligible for the service guarantee. Whether a quantitative value for CLR is specified is network specific.

2.3 Relationship between nrt-VBR, UBR, ABR, and GFR Service Categories

Four service categories are intended for non-real-time applications. They differ as to the nature of the service guarantees provided by the network and the mechanisms that are implemented in end-systems and networks to realize them. Selection of an appropriate service category is application specific.

2.3.1 Nature of Service Guarantees

The nrt-VBR service category provides commitments for a cell loss ratio for those connections that remain within the traffic contract negotiated with the network at the time the connection is established. The CLR for cells sent that do not conform to the traffic contract is not guaranteed. Also, some degree of isolation is assumed; that is, connections that exceed their traffic contract are expected not to cause the negotiated CLR to be exceeded on connections that do not exceed their traffic contract.

The UBR service category offers no traffic related service commitments. No numeric commitment is made as to the cell loss ratio experienced by a connection, or as to the cell transfer delay experienced by cells on the connection. Fairness among connections cannot be assumed, although local policy in some network elements may have this effect.

The ABR service category provides a low cell loss ratio for those connections whose end-stations obey a specified reference behavior. No numeric commitment is made about cell transfer delay. If the endpoints fail to observe the reference behavior, the cell loss ratio may degrade. Fairness among connections is assumed, modified by the MCR, local policy in network elements, and a potentially significant error term. Specific examples of fairness criteria are documented in Appendix I.3. A sufficient degree of isolation between connections is necessary so that connections that fail to observe the reference behavior do not cause quality degradation on connections that do observe the reference behavior.

With the GFR service category, the user may always send cells at a rate up to PCR, but the network only commits to carry cells in complete unmarked frames at MCR. Traffic in excess of MCR and MBS will be delivered within the limits of available resources. It is expected that GFR connections will have fair access to available resources. The fairness policy is network specific.

2.3.2 Mechanisms

The non-real-time VBR service category is inherently open loop and has a traffic contract. The traffic contract may be met by the source end-system by use of traffic shaping, and enforced by the network and/or destination end-system by use of UPC. It is assumed that resources are reserved in network nodes to meet the traffic contract and QoS commitments, and thus connection admission control is provided in the network. This document does not specify a flow-control scheme for nrt-VBR.

The UBR service category is inherently open loop. UBR is not subject to a specific traffic contract but may be subject to a local policy in individual switches and end-systems.

The ABR service is inherently closed loop. The source performs dynamic traffic shaping based on feedback received from the network. This behavior may be enforced by the network using UPC. A minimum cell rate (MCR) is negotiated. If the MCR is non-zero, then it is assumed that resources are reserved in network nodes to ensure that the feedback never causes the available cell rate to fall below the MCR, and that low CLR is achieved; thus, connection admission control may be provided in the network. Local policy in network elements contributes to fairness and isolation, with the objective of achieving low CLR for those connections that obey the source behavior.

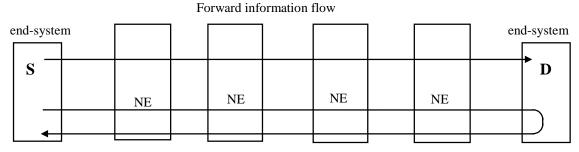

The GFR service category is inherently open loop and has a traffic contract. It is assumed that resources are reserved in network nodes to ensure that the minimum cell rate is available, and that low CLR is achieved for frames eligible for the service guarantee. Therefore, connection admission control may be provided in

the network. Functions such as scheduling and congestion control in the network elements can contribute to fairness and isolation.

2.4 Flow Control Model and Service Model for the ABR Service Category

2.4.1 Flow Control Model for ABR

ABR flow control occurs between a sending end-system (source) and a receiving end-system (destination). Sources and destinations are connected via bi-directional connections. For a bi-directional ABR connection, each connection termination point is both a source and a destination. For the sake of simplicity, only the information flow from the source to the destination with its associated RM-cell flows is considered. The forward direction is the direction from the source to the destination, and the backward direction is the direction from the destination to the source. As shown in Figure 2-1, for the forward information flow from the source to the destination, there is a control loop consisting of two RM-cell flows, one in the forward direction and one in the backward.

Control loop associated with forward information flow

S: Source
D: Destination
NE: Network Element

Figure 2-1: Example of a source to destination ABR control loop

A source generates forward RM-cells , which are turned around by the destination and sent back to the source as backward RM-cells. These backward RM-cells carry feedback information provided by the network elements and/or the destination back to the source. A network element may:

- Directly insert feedback control information into RM-cells when they pass in the forward or backward direction.
- Indirectly inform the source about congestion by setting the EFCI bit in the data cell header of the cells of the forward information flow. In this case, the destination will update the backward RM-cells based on this congestion information.
- Generate backward RM-cells.

2.4.2 Detailed Service Model for ABR

The following points summarize some properties of ABR service:

- A goal of ABR service is to provide rapid access to unused network bandwidth at up to PCR, whenever the network bandwidth is available.
- A reference behavior of the source end-system (Section 5.10.4), destination end-system (Section 5.10.5), and switch (Section 5.10.6) is specified. Performance commitments by the network will apply only for end-systems that follow the reference behavior. These performance commitments are in terms of a cell loss ratio that is network specific.
- An ABR end-station must always implement both the source and destination behavior.

- In ABR, user data cells shall have CLP=0. However RM-cells may have CLP=1. Since the CLR objectives for ABR cover only cells with CLP=0, the network may selectively discard RM-cells marked CLP=1. Tagging is currently not supported by ABR. It is for further study whether ABR may also use CLP=1 user data cells and whether tagging may be applied.
- The ABR service may apply to both VCCs and VPCs.
- A network element may divide an ABR connection into separately controlled segments by closing the feedback loop using the virtual source and virtual destination function described in Section 5.10.7. Segmentation may be desirable at administrative boundaries, or when the magnitude of round-trip delay differs between two segments, or due to the preferences of the network operator.
- Fairness: No set of connections should be arbitrarily discriminated against and no set of connections should be arbitrarily favored, although resources may be allocated according to a defined policy. The results of the bandwidth allocation process for ABR service approaches some fairness criteria. A number of fairness criteria are possible. See Appendix I.3 for examples.
- Acceptable values of Cell Loss Ratio are network specific. The objective is to minimize CLR provided the end-system adapts the traffic to the changing ATM layer transfer characteristics.
- The rate of any ABR flow has two components: an MCR component, which could be zero, for which there is a quantitative commitment made by the network, and an "elastic" component for which the commitment made by the network is only a relative assurance that bandwidth will be shared fairly among the ABR flows.
 - MCR is negotiated independently for each direction of a bi-directional ABR connection. A source is not precluded from sending at a rate less than MCR, when MCR > 0 is negotiated.
 - The actual cell rate at which the end-system may transmit is never less than MCR¹. The MCR agreed between the end-systems and the network(s) carrying the connection may range from zero to the maximum value supported by the network(s). This maximum may be zero. If the calling end-system does not indicate a requested MCR, the default value of MCR is zero.
 - The method for fairly allocating bandwidth after MCR commitments are met is an area for implementation latitude. However, whatever the interpretation, it must be consistent and predictable within a range of error. The ideal fair share of a connection in a given configuration can be calculated given global knowledge. This is described in detail in Appendix I.3.
 - If no connections have MCR requirements, and all connections are equally weighted², the max-min fairness criteria can be applied. Fairness cannot be observed in isolation by a user of the service. For non-zero MCR requirements and for the case of weighted allocation of bandwidth, other fairness criteria may apply.
- Although the network commits to support MCR, a source may receive indications to reduce its rate below MCR. If a source receives such indication and its rate is above MCR it should reduce its rate to MCR. Likewise, if a source receives such indication, and its rate is at or below MCR, the source need make no change to its rate.
- During a connection establishment for a connection with MCR=0, it is not expected that the CAC function will block the connection because of bandwidth (e.g., MCR) allocated to other connections. Blocking due to CAC for other reasons is not precluded.
- When ABR connections with MCR >0 are set up, they may block future requests for connections with MCR >0. The management of bandwidth allocation between ABR and other service categories is implementation dependent.

¹ See Section 5.10.2.2 for details on negotiating MCR.

²Weighted allocation implies that the available bandwidth can be divided in proportion to per connection weights. These weights could be equally related to MCR or independent of MCR.

• Because RM-cells cannot convey the EFCI code point, a switch that relies exclusively on EFCI feedback to convey its congestion state may (depending on implementation) be unable to effectively control the rate of in-rate RM-cells on a connection, during periods when no data cells are transmitted on the connection. In the absence of mechanisms to maintain control during such periods a network may choose to reserve a certain amount of bandwidth in order to increase the network's tolerance of the in-rate RM-cell stream. The amount of bandwidth reserved for this purpose is network specific and may support only a limited number of connections. This may result in rejection of setup requests including those with MCR=0.

One mechanism that can be used to maintain control of the in-rate RM-cell stream during periods when no data cells are transmitted on a connection is via switch behavior #1 b, "relative rate marking" (see Section 5.10.6).

2.4.2.1 Point-to-multipoint ABR Connections

The support of ABR point-to-multipoint connections is not required for ABR compliance as defined in this specification. However, the guidelines provided here are intended as a basic framework for a complete specification of point-to-multipoint ABR service in the future.

The defining characteristics of an ABR point-to-multipoint connection are its dynamic allocation of available bandwidth and its flow-controlled transport of data from the root to each responding leaf. Under one possible operation, achieving the latter characteristic requires the root of the tree to transmit data at a rate that the slowest branch can carry and that the slowest leaf can accept, although all branches and

leaves are expected to support a rate greater than or equal to the MCR of the connection at all times. Nevertheless, because the ABR source behavior requires a decrease in rates in the absence of feedback, strict adherence under all circumstances to the requirement for flow-controlled transport would result in the degradation of performance for the entire tree whenever a single leaf became unresponsive. Therefore, a branch may be designated as in the "non-responding state" if no RM-cells have been received from the branch for some time, the length of which is implementation specific but indicates the unavailability of the branch. The branch point need not consider the presence of branches in the non-responding state in sending feedback to the root, and cells lost on non-responding branches are not counted against cell-loss objectives.

Point-to-multipoint behavior is addressed in Section 5.10.8. Branch points, which must replicate cells traveling from root to leaves and consolidate feedback traveling from leaves to root, are functionally defined, but their operating policies are implementation specific. An ABR branchpoint should ensure that cell flows on its branches observe the same conformance definitions as point-to-point cell flows. It must replicate data and forward RM-cells, consolidate backward RM-cells, (to ensure that the volume of RM-cells returning to the source do not increase with the number of leaves in the tree), and it must support CLR objectives. Because the expected behavior of the ABR flow on a point-to-multipoint branch is the same as on a point-to-point connection, each branch and leaf must be prepared to accept cells at a rate greater than or equal to the negotiated MCR at all times.

The behavior of switches (located on a branch), sources and destinations (located at the root or at leaves), and of virtual sources and virtual destinations (located on a branch) are the same for multipoint operation as for point-to-point operation, except that data traffic is not allowed in the direction from the leaves to the root of the point-to-multipoint tree. Availability of bandwidth on the return path (from leaf towards root) is necessary for the propagation of return RM-cells. Hence, MCR > 0 and PCR > 0 are allowed for the return path. When MCR = PCR = 0 is used for the return path, only out-of-rate RM-cells are allowed, as specified in Section 5.10.8.1. The MCR (PCR) used from leaf to root may differ from the MCR (PCR) used from root to leaf, but must be the same for all leaves. The flow of data cells from the leaves to the root is precluded because data cells, unlike RM-cells, cannot be consolidated at branch points. The cell-loss ratio required of a point-to-multipoint ABR connection by some applications may depend on the size of the point-to-multipoint tree. Some applications need to retransmit a cell to all leaves whenever it does not successfully arrive at any leaf. For such applications, it is recommended that the CLR parameter, which applies at each interface to an individual leaf, should be chosen to control the probability of unsuccessful

delivery of each cell to one or more leaves. As an example, under the conservative assumption that the unsuccessful delivery of a given cell to each of *N* different leaves are independent events, the expected relationship between (a) the proportion CLR_total of cells transmitted by the root that are not successfully received by at least one leaf and (b) the CLR for each individual leaf is

$$CLR total = 1 - (1-CLR)^{N}$$

and CLR would be chosen accordingly.

The ABR branch point may segment the control loop by placing virtual sources at the interface to one or more branches and virtual destinations at the branches feeding them. The use of buffering at virtual sources allows the temporal decoupling of the feedback received from the leaves and transmitted to the root. It also allows the decoupling of the ABR parameters downstream and upstream of the branch point.

For delivery with low CLR within a subtree between virtual sources/destinations, the source parameters at the root must be chosen to accommodate all the branches allowed on the tree. Architectural options, beyond the use of virtual sources/virtual destinations, for further decoupling the ABR control loop include the use of multicast servers that terminate the ATM layer, but such options are beyond the scope of this document.

2.5 GFR Service Model

The Guaranteed Frame Rate (GFR) service is intended to support non-real-time applications. The GFR service category requires that the user data cells are organized in the form of frames that can be delineated at the ATM layer.

The GFR service category provides the user with a Minimum Cell Rate (MCR) guarantee under the assumption of a given maximum frame size (MFS) and a given Maximum Burst Size (MBS). The MFS and MBS are both expressed in units of cells.

The above service guarantee implies that if the user sends conforming frames (see Section 4.5.5.1) in a burst that does not exceed the MBS, then the user should expect to see its frames delivered across the network with minimum losses. The GFR service also allows the user to send in excess of the MCR and the associated MBS, but the excess traffic will only be delivered within the limits of available resources. Furthermore, the service specifies that the excess traffic from each user should have access to a fair share of the available resources. The definition of fair share is implementation specific.

The user can send frames either unmarked or marked³. An unmarked frame is one in which all cells have CLP=0; a marked frame is one in which all cells have CLP=1. The CLP must be the same for all cells in a frame. By sending a frame marked, the user indicates to the network that such a frame is of lesser importance than an unmarked frame. The MCR guarantee only applies to unmarked frames. The network is only allowed to tag cells in unmarked frames if the user has requested the tagging option, either via signaling (for SVCs) or via subscription (for PVCs). Otherwise, tagging by the network is not applicable.

The GFR service category does not give to the users explicit feedback regarding the current level of network congestion. Currently, the GFR service category only applies to virtual channel connections, because frame delineation is not generally visible in a virtual path connection.

The above service definition allows a user to expect a minimum service rate when the network is congested, while being able to send at a higher rate when additional resources are available.

 $^{^3}$ A cell is called marked or unmarked when the originator of the cell has set its CLP bit to one or zero, respectively. A cell is called tagged when the network has set its CLP bit to one.

3. ATM Layer Quality of Service

The ATM layer Quality of Service (QoS) is measured by a set of parameters characterizing the performance of an ATM layer connection. These QoS parameters quantify end-to-end network performance at the ATM layer. In ITU-T Recommendation I.356, they are referred to as network performance parameters.

3.1 Quality of Service Parameters

Six QoS parameters that correspond to network performance objectives are identified in this specification. Three of these may be negotiated between the end-systems and the networks. One or more values of the QoS parameters may be offered on a per connection basis, corresponding to the number of related performance objectives supported by the network. Support of different performance objectives can be done by routing the connection to meet different objectives, or by implementation-specific mechanisms within individual network elements. The following QoS parameters are negotiated:

- Peak-to-peak Cell Delay Variation (peak-to-peak CDV)
- Maximum Cell Transfer Delay (maxCTD)
- Cell Loss Ratio (CLR)

The following QoS parameters are not negotiated:

- Cell Error Ratio (CER)
- Severely Errored Cell Block Ratio (SECBR)
- Cell Misinsertion Rate (CMR)

Further information on ATM layer QoS may be found in ITU-T Recommendation I.356.

3.2 Nature of QoS Commitments

A network may support one or more performance objectives for each of the QoS parameters. For each direction of a connection, a specific QoS is negotiated among the network(s) and the end-systems. The network agrees to meet or exceed the negotiated QoS as long as the end-system complies with the negotiated traffic contract (see Section 4.2 and ITU-T Recommendation I.371).

QoS commitments are probabilistic in nature, and are intended to be only a first order approximation of the performance that the network expects to offer over the duration of the connection. Since there is no limit to the duration of connections, and the network can only make decisions based on information available at the time the connection is established, the actual QoS may vary over the duration of the connection. In particular, transient events (including uncontrollable impairments in transmission systems) can cause short term performance observations to be worse than the agreed QoS commitment. Thus, QoS commitments can only be evaluated over the long term and over multiple connections with similar QoS commitments.

The precision with which the various QoS values can be coded may be significantly greater than the accuracy with which the network can predict, measure or maintain a given performance level. Thus, the number of significant digits in the encoding of the QoS parameters that are expressed as numeric values (rather than orders of magnitude) should not be misconstrued as a commitment to that level of precision in performance management

3.3 Negotiation of OoS Parameters

The mechanisms whereby QoS may be negotiated between the end-system and the network in quantified numeric units are defined in UNI Signaling 4.0 and PNNI 1.0. These mechanisms supplement the "QoS class" procedures defined in UNI 3.1 and ITU-T Recommendation I.356. Implementations must at a minimum support QoS indication via QoS classes. In addition implementations capable of stating QoS in terms of individual numeric parameter values may do so using the procedures defined in UNI Signaling 4.0 and PNNI 1.0.

3.4 Terminology

3.4.1 Cell Events

The following two events are defined based on ITU-T Recommendation I.356. These events will be used in defining the QoS performance parameters.

- A "cell exit event" occurs when the first bit of an ATM cell has completed transmission out of an
 end-system to a Private ATM network element across the "Private UNI" Measurement Point, or out of
 a Private ATM network element to a Public ATM network element across the "Public UNI"
 Measurement Point, or out of an ATM end-system to a Public ATM network across the "Public UNI"
 Measurement Point.
- A "cell entry event" occurs when the last bit of an ATM cell has completed transmission into an
 end-system from a Private ATM network element across the "Private UNI" Measurement Point, or
 into a Private ATM network element from a Public ATM network element across the "Public UNI"
 Measurement Point or into an ATM end-system from a Public ATM network element across the
 "Public UNI" Measurement Point.

3.4.2 Cell Transfer Outcome

The following possible cell transfer outcomes between measurement points for transmitted cells are defined based on ITU-T Recommendation I.356:

- Successful Cell Transfer Outcome: The cell is received corresponding to the transmitted cell within a
 specified time T_{max}. The binary content of the received cell conforms exactly to the corresponding
 transmitted cell payload and the cell is received with a valid header field after header error control
 procedures are completed.
- Errored Cell Outcome: The cell is received corresponding to the transmitted cell within a specified time T_{max}. The binary content of the received cell payload differs from that of the corresponding transmitted cell payload or the cell is received with an invalid header field after header error control procedures are completed.
- Lost Cell Outcome: No cell is received corresponding to the transmitted cell within a specified time
 T_{max}. (Examples include "never received" or "late".)
- Misinserted Cell Outcome: A cell is received for which there is no corresponding transmitted cell.
- Severely-Errored Cell Block Outcome: When *M* or more Lost Cell outcomes, Misinserted Cell Outcomes, or Errored Cell outcomes are observed in a received cell block of *N* cells transmitted consecutively on a given connection.

3.5 QoS Reference Configuration

QoS parameters are defined at measurement points that coincide with interfaces shown in Figure 3-1.

Quantitative values for performance objectives are not defined in this document. However, alternative means to measure, or estimate the value of defined performance parameters will be described. QoS performance of switches and QoS performance objectives of networks are stated in terms of the parameters defined in this section.

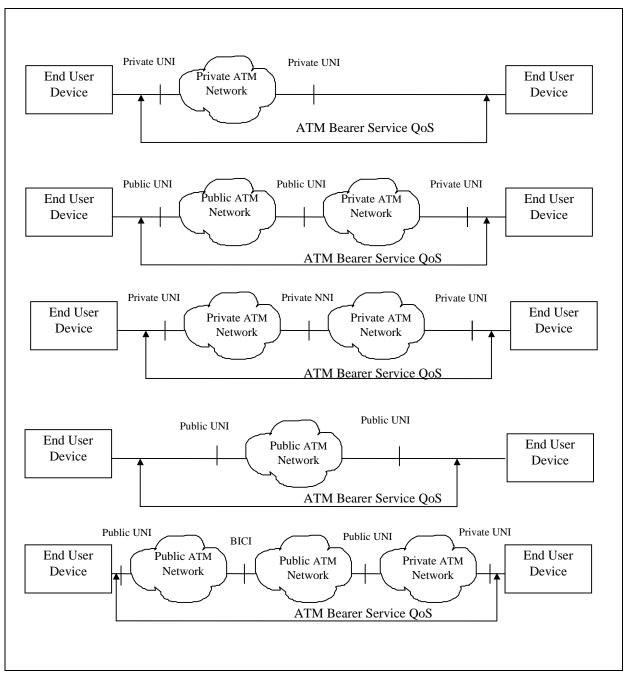

Figure 3-1: ATM QoS Reference Configurations

3.6 Definition of Negotiated OoS Parameters

This section describes QoS parameters that may apply to a connection. These parameters are defined in terms of:

- a) a method for measuring the transfer characteristics of the network as observed on a single ATM cell (or a sequence of ATM cells) during the lifetime of an ATM virtual connection, and
- b) a statistical objective that is negotiated, such that the network agrees to meet at least the value negotiated over a large sample of cells.

Measurements are useful for determining network performance (including determination of whether negotiated statistical objectives for the connection are being met). Measurements occur at measurement points, as defined in ITU-T Recommendation I.356.

One or more measurements and one or more objectives apply to each relevant aspect of QoS. The measurement of network performance on a virtual connection is likely to be different from the negotiated objective for the connection at any given time. This is because:

- The negotiated objective is the worst case of network performance (measured over a sample of cells that is appropriately large for the given QoS parameter) that the network will allow, including periods of peak loading. The mechanisms described in Section 5 are used to ensure that the QoS experienced by existing connections meets at least the negotiated objective. During periods when network loading is much less than the engineered capacity, the measured performance may be significantly better than the negotiated objective.
- Transient events can cause the measured performance of a connection to be worse than the negotiated objective, when a measurement is inappropriately used over an insufficiently large sample of cells.

3.6.1 Delay Parameters

The measured Cell Transfer Delay (CTD) is defined as the elapsed time between a cell exit event at measurement point 1 (MP₁) (e.g., at the source UNI) and the corresponding cell entry event at measurement point 2 (MP₂) (e.g., the destination UNI) for a particular connection. The Cell Transfer Delay between two measurement points is the sum of the total inter-ATM node transmission delay and the total ATM node processing delay between MP₁ and MP₂. The various components of the Cell Transfer Delay are described in more detail in Annex B of I.356.

Two end-to-end delay parameter objectives are negotiated:

- peak-to-peak CDV
- maxCTD.

Figure 3-2 below illustrates the probability density function of the CTD in CBR and real-time VBR services, and relates it to the peak-to-peak CDV and maxCTD parameters.

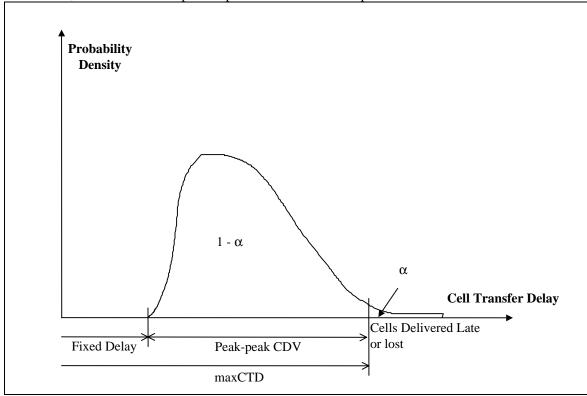

Figure 3-2: Cell transfer delay probability density model (for real-time service categories)

The components of the fixed delay include propagation through the physical media, delays induced by transmission system, and fixed components of switch processing delay. CDV is induced by buffering, cell scheduling and the variable components of switch processing delay.

3.6.1.1 Maximum Cell Transfer Delay (maxCTD)

The maximum Cell Transfer Delay (maxCTD) specified for a connection is the $(1 - \alpha)$ quantile of CTD. The CLR at connection request time is used to place an upper bound on α . When a switch accumulates maxCTD or CDV it may choose a smaller α which may have the effect of over-estimating the cumulative maxCTD or CDV. The assumed relationship between CLR and α is for further study. Refer to UNI Signaling 4.0 for the coding of maxCTD.

3.6.1.2 Cell Delay Variation (CDV)

Two measurement methods are defined for CDV. These are:

- One-point cell delay variation (one-point CDV)
- Two-point cell delay variation (two-point CDV).

The negotiated objective for CDV performance is expressed in terms of peak-to-peak CDV. Note: The QoS parameter CDV should not be confused with the connection traffic parameter CDVT (see Section 4.4.1).

3.6.1.2.1 One-Point CDV

The one-point CDV describes the variability in the pattern of cell arrival events observed at a single measurement point with reference to the negotiated peak rate 1/T (as defined in ITU-T Recommendation I.371).

The one-point CDV for cell k (y_k) at a measurement point is defined as the difference between the cell's reference arrival time (c_k) and actual arrival time (a_k) at the measurement point: $y_k = c_k - a_k$. The reference arrival time (c_k) is defined as follows:

$$c_0 = a_0$$

$$c_{k+1} = \begin{cases} a_k + T & \text{if } c_k \leq a_k \\ c_k + T & \text{otherwise} \end{cases}$$

Positive values of the one-point CDV correspond to cell clumping; negative values of the one-point CDV correspond to gaps in the cell stream. The reference arrival time defined above eliminates the effect of gaps and provides a measurement of cell clumping.

3.6.1.2.2 Two-Point CDV

The two-point CDV describes the variability in the pattern of cell arrival events observed at the output of a connection portion (MP_2) with reference to the pattern of the corresponding events observed at the input to the connection portion (MP_1) .

The two-point CDV for cell k (v_k) between two measurement points (MP₁ and MP₂) is the difference between the absolute cell transfer delay of cell k (x_k) between the two MPs and a defined reference cell transfer delay ($d_{1,2}$) between MP₁ and MP₂: $v_k = x_{k^-} d_{1,2}$.

The absolute cell transfer delay (x_k) of cell k between MP_1 and MP_2 is the same as Cell Transfer Delay defined in Section 3.6.1. The reference cell transfer delay $(d_{1,2})$ between MP_1 and MP_2 is the absolute cell transfer delay experienced by a reference cell between the two MP_3 .

ITU-T Recommendation I.356 provides more details on the CDV measurements.

3.6.1.2.3 Peak-to-peak Cell Delay Variation (peak-to-peak CDV)

The peak-to-peak CDV is the difference between the $(1-\alpha)$ quantile of the CTD and the fixed CTD that could be experienced by any delivered cell on a connection during the entire connection holding time. The term "peak-to-peak" refers to the difference between the best and worst case of CTD, where the best case is equal to the fixed delay, and the worst case is equal to a value likely to be exceeded with probability no greater than α . Assuming that the fixed delay is the reference delay for the two point CDV, the range of the distribution of the two-point CDV is the same as the peak-to-peak CDV. Refer to UNI Signaling 4.0 for the coding of peak-to-peak CDV.

Networks have a finite ability to control peak-to-peak CDV. Therefore, end-systems cannot expect to negotiate arbitrarily small values of peak-to-peak CDV as their sole means of meeting jitter and wander tolerances (as specified in ITU-T Recommendations G.822 and G.823).

3.6.2 Accumulation of QoS Parameters

This section specifies accumulation algorithms for the two delay parameters, maxCTD and peak-to-peak CDV. These algorithms are intended to be used in path calculations and to accumulate delay parameters in signaling protocols as a call progresses. As a result, the accumulation algorithms provide estimates of the end-to-end values of these parameters along a path. A simple accumulation based on worst case assumptions is supported in this specification.

The simple accumulation for peak-to-peak CDV is the following: A switch receives the accumulated peak-to-peak CDV and adds its contribution of the peak-to-peak CDV(α) to the accumulated peak-to-peak CDV.

The simple accumulation for maxCTD is the following: A switch receives the accumulated maxCTD and adds its contribution of the maxCTD(α) to the accumulated maxCTD.

In signaling, maxCTD is accumulated only in the forward direction (maxCTD_F). However, the CDV is accumulated in both forward and backward directions (CDV_F, CDV_B). Consequently the maxCTD for the backward direction is derivable as:

$$maxCTD_{_{B}} = CDV_{_{B}} + maxCTD_{_{F}} - CDV_{_{F}}$$

This is because the fixed delay in the forward direction (maxCTD $_{\scriptscriptstyle F}$ - CDV $_{\scriptscriptstyle F}$) is the same as the fixed delay in the reverse direction (maxCTD $_{\scriptscriptstyle B}$ - CDV $_{\scriptscriptstyle B}$).

3.6.3 Dependability Parameters

One end-to-end dependability parameter is presently negotiated:

• Cell Loss Ratio (CLR)

This end-to-end dependability parameter applies to all service categories except the Unspecified Bit Rate (UBR) service. For Available Bit Rate (ABR) and Guaranteed Frame Rate (GFR) services the CLR is not negotiated; see sections 3.7.1.4 and 3.7.1.5.

3.6.3.1 Cell Loss Ratio (CLR)

The Cell Loss Ratio is defined for a connection as:

$$CLR = \frac{Lost Cells}{Total Transmitted Cells}$$

Lost and transmitted cells counted in severely errored cell blocks should be excluded from the cell population in computing cell loss ratio.

The CLR parameter is the value of CLR that the network agrees to offer as an objective over the lifetime of the connection. Refer to UNI Signaling 4.0 for the coding of CLR.

The CLR objective applies either to the CLP=0 cell flow or to the aggregate CLP=0+1 cell flow, as determined by the applicable conformance definition in Section 4.5.

If frame discard is enabled for a connection, conforming cells may be discarded to enhance performance. In this case, the CLR is not a reliable measure of service performance.

If frame discard is enabled Frame Loss Ratio is defined as:

$$FLR = \frac{Lost\ Frames + Corrupted\ Frames}{Total\ Transmitted\ Frames},$$

where "Lost Frames" refers to complete dropped frames and "Corrupted Frames" refers to partial dropped frames.

Frame Loss Ratio is not a negotiated QoS parameter.

3.6.4 Accumulation of Dependability Parameters

The CLR parameter is not explicitly accumulated. Each network element accepts or rejects the call based on a comparison between the loss rate supported by the network element and the requested CLR. Details of the CAC are network specific. See UNI Signaling 4.0 for details of CLR signaling.

3.7 Non-negotiated QoS Parameters

3.7.1 Dependability Parameters

3.7.1.1 Cell Error Ratio

The Cell Error Ratio (CER) is defined as follows for a connection:

$$CER = \frac{Errored \, Cells}{Successfully \, Transferred \, Cells + Errored \, Cells}$$

Successfully transferred cells and errored cells contained in cell blocks counted as severely errored Cell Blocks should be excluded from the population used in calculating cell error ratio.

3.7.1.2 Severely Errored Cell Block Ratio

The Severely Errored Cell Block Ratio (SECBR) is defined as follows for a connection:

$$SECBR = \frac{Severely Errored Cell Blocks}{Total Transmitted Cell Blocks}$$

A cell block is a sequence of N cells transmitted consecutively on a given connection. A severely errored cell block outcome occurs when more than M errored cells, lost cells, or misinserted cell outcomes are observed in a received cell block.

For practical measurement purposes, a cell block will normally correspond to the number of user information cells transmitted between successive OAM cells. Refer to ITU-T Recommendation I.610 for the size of cell blocks.

If frame discard is enabled for a connection, the number of lost cells may increase and affect the SECBR. The frame size should therefore be considered when defining the parameters M and N.

3.7.1.3 Cell Misinsertion Rate

The Cell Misinsertion Rate (CMR) is defined as follows for a connection:

$$CMR = \frac{Misinserted Cells}{Time Interval}$$

Severely Errored Cell Blocks should be excluded from the population when calculating the cell misinsertion rate. Cell misinsertion on a particular connection is most often caused by an undetected error in the header of a cell being transmitted on a different connection. This performance parameter is defined as a rate (rather than the ratio) since the occurrence of misinserted cells is independent of the number of transmitted cells received on the corresponding connection.

3.7.1.4 CLR for the ABR Service Category

The Cell Loss Ratio for the ABR service category is not a negotiated parameter. For the definition of CLR see Section 3.6.3.1.

3.7.1.5 CLR for the GFR Service Category

The Cell Loss Ratio for the GFR service category is not a negotiated parameter. For the definition of CLR see Section 3.6.3.1. CLR is low for frames that are eligible for the service guarantee. Whether a quantitative value for CLR is specified is network specific.

4. Traffic Contract

4.1 Traffic Parameters and Descriptors

Traffic parameters describe traffic characteristics of a source. For a given connection, traffic parameters are grouped into a source traffic descriptor, which in turn is a component of a connection traffic descriptor. These terms are defined below.

4.1.1 Traffic Parameters

A traffic parameter describes an inherent characteristic of a traffic source. It may be quantitative or qualitative. Traffic parameters defined in this specification include Peak Cell Rate (PCR), Sustainable Cell Rate (SCR), Maximum Burst Size (MBS), Minimum Cell Rate (MCR), and Maximum Frame Size (MFS).

4.1.2 Source Traffic Descriptor

A source traffic descriptor is the set of traffic parameters of the ATM source. It is used during the connection establishment to capture the intrinsic traffic characteristics of the connection requested by a particular source. Section 2.2 identifies a relationship between source traffic descriptors and ATM service categories.

4.1.3 Connection Traffic Descriptor

The connection traffic descriptor specifies the traffic characteristics of the ATM connection. The connection traffic descriptor includes the source traffic descriptor, the CDVT, and the conformance definition that is used to unambiguously specify the conforming cells of the connection. CAC procedures may use the connection traffic descriptor to allocate resources and to derive parameter values for the operation of the UPC. The connection traffic descriptor contains the necessary information for conformance testing of cells of the connection at the UNI. These traffic parameters (and any new traffic parameters that may be defined in future specifications) should fulfill the following requirements:

- be understandable by the end-system; conformance testing should be possible.
- be useful in resource allocation schemes meeting network performance requirements.
- be enforceable by the UPC.

These criteria should be respected since end-systems may have to provide these traffic parameters and CDVT at connection establishment. In addition, the connection traffic descriptor should be useful to the CAC procedure so that network performance objectives can be maintained once the connection is accepted. Finally, they should be enforceable by the UPC in order to maintain network performance.

4.2 Traffic Contract Specification

A traffic contract specifies the negotiated characteristics of a connection.

- (**R**) The traffic contract at the Public UNI shall consist of a connection traffic descriptor and a set of QoS parameters for each direction of the connection and shall include the definition of a compliant connection.
- (O) The Private UNI may optionally support the same traffic contract as the Public UNI or a different traffic contract.

The connection traffic descriptor consists of all parameters and the conformance definition used to specify unambiguously the conforming cells of the connection, i.e.:

- the source traffic descriptor (i.e., PCR, SCR, MBS, MFS, and MCR),
- the CDVT,
- the conformance definition.

For CBR, rt-VBR, nrt-VBR, and UBR, a conformance definition based on the GCRA is used to unambiguously specify the conforming cells of a connection at the UNI. See Section 4.4.2 for further details on the conformance definition. Examples of conformance definitions using the GCRA are provided in Appendix II. For ABR, the conformance definition refers to the behavior specified for ABR sources, destinations, and switches, but allows for delays between the source and the UNI, which may perturb the traffic flow. For GFR, the conformance definition includes a GCRA and other considerations. See Section 4.5.5 for more information on GFR conformance.

The conformance definition should not be interpreted as the UPC algorithm. For example, although cell conformance at the UNI is defined by the conformance definition based on the GCRA for CBR, rt-VBR, and nrt-VBR, the network may use any UPC algorithm, as long as the operation of the UPC does not violate the QoS objectives of compliant connections.

The values of the traffic contract parameters can be specified either explicitly or implicitly. A parameter value is explicitly specified when its value is assigned by the end-system using signaling for SVCs, or when it is specified by the Network Management System (NMS) for PVCs. A parameter value specified at subscription time is also considered to be explicitly specified. A parameter value is implicitly specified when its value is assigned by the network using default rules, which in turn depend on the information explicitly specified by the end-system. A default rule is a rule used by a network to assign a value to a traffic contract parameter that is not explicitly specified. In the case where no default rules are specified, they are network specific.

The CAC and UPC procedures are network specific and should take into account the knowledge of the specified traffic contract to operate efficiently.

In order to accommodate additional, experimental traffic parameters at the UNI, signaling messages have the capability to encode network specific information elements. See UNI Signaling 4.0 for details.

For OAM cell flows across the UNI, the network may require the user to specify traffic parameters for the OAM traffic of an ATM connection. Traffic parameters for OAM cell flow across the UNI may be explicitly specified at subscription time, or implicitly by a default rule.

(**R**) At the service subscription time, the network shall negotiate the upper limit on the OAM traffic as a function of the connection traffic descriptor for the user data traffic of an ATM connection.

4.3 Cell Conformance and Connection Compliance

Conformance applies to cells as they pass the UNI and are, in principle, tested according to some algorithm. The first cell of the connection initializes the algorithm and from then on each cell is either conforming or non-conforming. Even under ideal conditions some cells may be non-conforming. Therefore it is inappropriate for the network to only commit to the QoS objectives for those connections for which all cells are conforming. In effect, connection compliance does not imply that all cells associated with the connection are conforming.

4.3.1 Compliance for CBR, rt-VBR, nrt-VBR, and UBR

(**R**) The precise definition of a compliant CBR, rt-VBR, nrt-VBR, or UBR connection is network specific. However, it is required that any definition of a compliant connection for these services shall identify a connection for which all cells are conforming to be a compliant connection.

Based on actions of the UPC function, the network may decide whether or not a connection is compliant. The network commits to support the QoS for all connections that are compliant.

(**R**) For CBR, rt-VBR, nrt-VBR, and UBR connections that are compliant at the UNI, the agreed QoS objective shall be supported for at least the number of cells equal to the number of conforming cells according to the conformance definition.

For non-compliant connections, the network does not need to respect the agreed QoS objective. The conformance definition defines conformity at an interface according to one or more instances of the GCRA

algorithm as specified in Section 4.5. For example, the conformance definition may use two instances of GCRA, once for PCR of the aggregate (CLP=0+1) cell stream and once for the SCR of the CLP=0 cell stream. Appendix II provides more details and further examples of the conformance definition for CBR, rt-VBR, rrt-VBR and UBR connections. The network may offer a limited set of alternative conformance definitions (all based on the GCRA) from which the end-system may choose for a given connection.

4.3.2 Compliance for ABR

For ABR connections conformance applies to CLP=0 cells, which are tested upon their arrival at the UNI. At this point each cell is then identified either as conforming or non-conforming. For a PVC, after reinitialization of a source, some cells may be judged as non-conforming.

(R) The precise definition of a compliant ABR connection is network specific. An ABR connection whose cells all conform (see Section 4.5.4) and whose RM-cells are received in relation to one another and to other cells as specified in Section 5.10 is a compliant connection.

Appendix III.4 has examples of tests for the compliant generation of RM-cells.

- (R) For compliant ABR connections at the Public UNI, the agreed QoS objectives shall be supported for at least the number of cells equal to the number of conforming cells.
- (**R**) The conformance and compliance definitions used at an interface shall be the same for point-to-multipoint connections as for point-to-point connections, except that data cells are not allowed on point-to-multipoint connections in the direction from the leaves to the root.

4.3.3 Compliance for GFR

(R) The precise definition of a compliant GFR connection is network specific. However, a connection for which all cells are conforming shall be defined to be compliant. For compliant GFR connections, the network commits to provide a low cell loss ratio for cells of frames defined as eligible for the service guarantee. Refer to Section 4.5.5 for more information on GFR conformance and service eligibility.

4.4 Traffic Contract Parameters and Related Algorithms

4.4.1 Cell Delay Variation Tolerance (CDVT) for PCR and SCR

ATM layer functions (e.g., cell multiplexing) may alter the traffic characteristics of connections by introducing Cell Delay Variation. When cells from two or more connections are multiplexed, cells of a given connection may be delayed while cells of another connection are being inserted at the output of the multiplexer. Similarly, some cells may be delayed while physical layer overhead or OAM cells are inserted. Consequently with reference to the peak emission interval T (i.e., the inverse of the contracted PCR), some randomness may affect the inter-arrival time between consecutive cells of a connection (i.e., the inverse of the contracted PCR) as monitored at the UNI (public or private). The upper bound on the "clumping" measure is the CDVT. A few examples that illustrate the allowed cell clumping are given in Annex B.3.

Similarly, with reference to the sustained emission interval T_s (i.e., the inverse of the contracted SCR), some randomness may affect the inter-arrival time between consecutive cells of a connection (i.e., the inverse of the contracted SCR) as monitored at the UNI (public or private).

The CDVT allocated to a particular connection at the private UNI (denoted by CDVT*) represents at this interface a bound on the connection cell clumping phenomenon due to the slotted nature of ATM, the physical layer overhead, and the ATM layer functions, i.e., cell multiplexing performed within the end-system. The CDVT allocated to a particular connection at the public UNI (denoted by CDVT) represents at this interface a bound on the connection cell clumping phenomenon due to the slotted nature of the ATM, the physical layer overhead, and the ATM layer functions performed within the private network equipment before the public UNI.

CDVT and CDVT* may impact the allocation of network resources for a connection. It is therefore recommended that both the CDVT and CDVT* be upper-bounded.

- (R) An end-system shall explicitly or implicitly select a value for the CDVT at the public UNI for an ATM connection from a set of values supported by the network. Whether the set of values is to be standardized or to be determined by the network is for further study.
- (R) The CDVT shall be explicitly specified at the PNNI, BICI, and at the UNI: CDVT and CDVT* are specified at subscription time.

Note: Signaling for CDVT or CDVT* is desirable from a traffic management viewpoint, but not supported in UNI Signaling 4.0.

4.4.2 Generic Cell Rate Algorithm (GCRA)

The GCRA is used to define conformance with respect to the traffic contract. For each cell arrival, the GCRA determines whether the cell conforms to the traffic contract of the connection. The UPC function may implement the GCRA, or one or more equivalent algorithms to enforce conformance. Although traffic conformance is defined in terms of the GCRA, the network is not required to use this algorithm (or the same parameter values) for the UPC. Rather, the network may use any UPC as long as the operation of the UPC supports the QoS objectives of a compliant connection.

The GCRA is a virtual scheduling algorithm or a continuous-state Leaky Bucket Algorithm as defined by the flowchart in Figure 4-1. The GCRA is used to define, in an operational manner, the relationship between PCR and the CDVT, and the relationship between SCR and the Burst Tolerance (BT). The BT can be derived from PCR, SCR, and MBS according to Annex B.4. In addition, the GCRA is used to specify the conformance, at the public or private UNI, of the declared values of the above two tolerances, as well as declared values of the traffic parameters PCR and SCR and MBS. See Section 4.4.3.2 and Annex B.4 respectively.

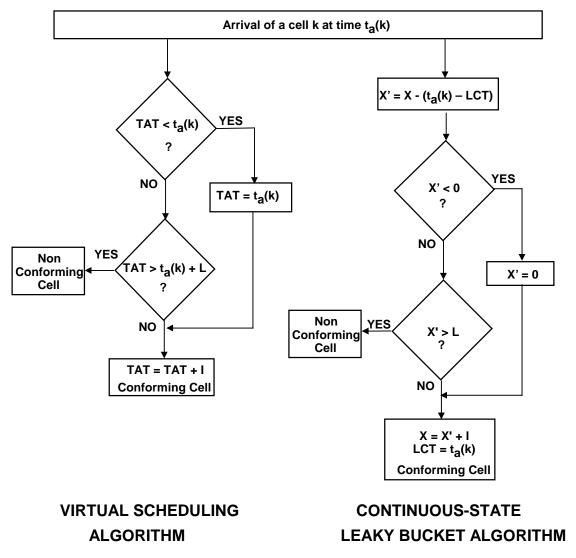

The GCRA is defined with two parameters: the Increment (I) and the Limit (L). The notation "GCRA(I, L)" means the Generic Cell Rate Algorithm with the value of the increment parameter set equal to I and the value of the limit parameter set equal to L. Note: I and L are not restricted to integer values. The GCRA is formally defined in Figure 4-1. Figure 4-1 is a generic version of Figure 1 in Annex 1 of I.371. The two algorithms in Figure 4-1 are equivalent in the sense that for any sequence of cell arrival times, $\{t_a(k), k >= 1\}$, the two algorithms determine the same cells to be conforming and thus the same cells to be non-conforming. The two algorithms are easily compared by noticing that at each arrival epoch, $t_a(k)$, and after the algorithms have been executed, TAT = X + LCT, as in Figure 4-1. An explanation of each algorithm is given in Annex B.1.

Multiple instances of the GCRA with possibly different I and L parameters may be applied to multiple flows (CLP=0 and CLP=0+1) of the same connection, or to the same flow. A cell is then conforming only if it conforms to all instances of the GCRA against which cells with its CLP state are tested. For example, if one instance of the GCRA tests the CLP=0 flow and one instance tests the CLP=0+1 flow, then a CLP=0 cell is conforming only if it conforms to both instances of the GCRA. In this same configuration, a CLP=1 cell is conforming only if it conforms to the instance of the GCRA that tests the CLP=0+1 flow. If tagging is used, a tagged cell is conforming only if it conforms as a CLP=1 cell. The state of a particular instance of the GCRA is updated only by the cells that conform as part of a flow tested by that instance of the GCRA. For example, a conforming tagged cell will not update the state of an instance of the GCRA that tests the CLP=0 flow, since the tagged cell conforms as a CLP=1 cell. Detailed flow-charts illustrating the interaction between multiple instances of the GCRA algorithm are given in ITU-T Recommendation I.371.

4.4.3 Peak Cell Rate Conformance

The Peak Cell Rate (PCR) traffic parameter specifies an upper bound on the rate at which traffic can be submitted on an ATM connection. Enforcement of this bound by the UPC allows the network to allocate

sufficient resources to ensure that the network performance objectives (e.g., for Cell Loss Ratio) can be achieved.

TAT	Theoretical Arrival Time	X	Value of the Leaky Bucket counter
t _a (k)	Time of arrival of a cell	X'	auxiliary variable
		LCT	Last Conformance Time

I Increment
L Limit

At the time of arrival t_a of the first cell of the connection, TAT = $t_a(1)$

At the time of arrival t_a of the first cell of the connection, X = 0 and LCT = $t_a(k)$

Figure 4-1: Equivalent versions of the Generic Cell Rate Algorithm

In the signaling message, the PCR is coded in cells per second (see UNI Signaling 4.0). The defined coding for the PCR in the signaling message does not imply that any UPC mechanism has to support the same linear granularity for the PCR across the complete defined cell rate range.

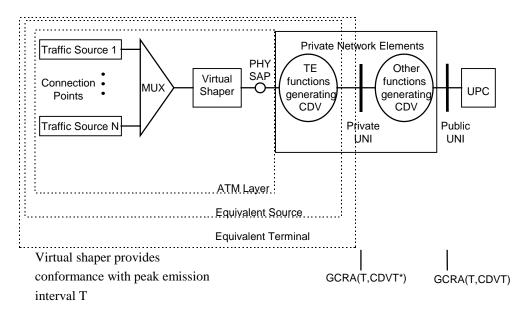

Figure 4-2: PCR Reference Model

4.4.3.1 PCR Reference Model

The equivalent-terminal configuration is given in Figure 4-2. It provides an abstract framework for describing the UPC at the public UNI. A similar model applies when UPC is implemented at the private UNI. Traffic sources, the multiplexer and the shaper define the equivalent-terminal. This is an abstraction that does not preclude any particular implementation of the end-system. This figure shows one or more private network elements that contain ATM layer switching and/or multiplexing, and therefore contribute to CDV, as observed at the public UNI.

All traffic sources (AALs, etc.) offering cells to a connection are put together in the equivalent-terminal. Each source generates requests to send ATM cells at its own rate. All requests are multiplexed in a Multiplexer (MUX in Figure 4-2) before entering the virtual shaper.

The virtual shaper is intended to reflect some smoothness in the cell flow offered to the connection: at the PHY_SAP, the minimal inter-arrival time between two consecutive requests is greater than or equal to T, which is called the peak emission interval of the connection. The output of the virtual shaper at the PHY_SAP of the equivalent-terminal conforms to GCRA(T, 0). This conformity cannot be required at the Private or Public UNIs since CDV is allowed in the private network elements as well as in the end-system. The output of the virtual shaper is affected by functions in the equivalent-terminal that cause CDV characterized by CDVT*. The value of CDVT* is chosen such that the output cell flow conforms to GCRA(T, CDVT*).

The output of the equivalent-terminal is affected by functions in other CPE that may modify the CDV at the Public UNI characterized by CDVT. The value of CDVT is chosen such that the output cell flow conforms to GCRA(T, CDVT).

The value of the peak emission interval T is user specific to allow for intelligent multiplexing within the end-system. For instance, AALs producing sporadic traffic may be synchronized to share the same transmission capacity. In other cases, T may be set to account for the combined activity of all traffic sources, e.g., the PCR of a VPC may be the sum of the PCRs of the VCCs contained in the VPC.

The PCR traffic parameter is defined at the PHY_SAP within an equivalent-terminal. The CDVT specified at the private UNI (CDVT*) (i.e., that directly connects an end-system to a private network) accounts for the cell clumping introduced by the end-system. The CDVT specified at the public UNI (CDVT) (i.e., that

connects an end-system to a public network through a private ATM network via a private UNI) accounts for the cell clumping introduced by the end-system and the private ATM network.

4.4.3.2 PCR Parameter Definition

The following definition applies to connections supporting CBR, rt-VBR, nrt-VBR, ABR, UBR, and GFR services.

The PCR definition for a connection is as follows:

- **Location:** At the PHY_SAP in an equivalent-terminal representing the connection (this is only a reference configuration; see Figure 4-2)
- **Basic Event**: Request to send an ATM_PDU in the equivalent-terminal.
- **Definition:** The PCR of the ATM connection is the inverse of the minimum inter-arrival time T between two basic events above. T is called the peak emission interval of the connection.

An interpretation of the definition of PCR and the equivalent terminal is given in Annex B.2.

4.4.3.3 CDVT

As shown in Figure 4-2, the CDVT is defined in relation to the PCR according to the GCRA. In particular, the CDVT at the public UNI, is defined in relation to the PCR according to the algorithm GCRA(T, CDVT), where T is the inverse of PCR. Likewise, the CDVT at the private UNI, CDVT*, is defined in relation to the PCR according to the algorithm GCRA(T, CDVT*).

4.4.4 Sustainable Cell Rate and Burst Tolerance

The SCR is an upper bound on the average rate of the conforming cells of an ATM connection, over time scales that are long relative to those for which the PCR is defined. Enforcement of this bound by the UPC could allow the network to allocate sufficient resources, but less than those based on the PCR, and still ensure that the performance objectives (e.g., for Cell Loss Ratio) can be achieved.

Note: ITU-T Recommendation I.371 refers to Burst Tolerance as Intrinsic Burst Tolerance (IBT).

4.4.4.1 SCR and BT Reference Model

The SCR Reference Model is defined with reference to Figure 4-3. The SCR and BT traffic parameters are defined at the PHY_SAP within an equivalent-terminal.

4.4.4.2 SCR and BT Definitions

The following definition applies to connections supporting rt-VBR and nrt-VBR services. The SCR and BT parameters for a connection are defined according to the GCRA (Section 4.4.2) as follows:

- **Location:** At the PHY_SAP in an equivalent-terminal representing the connection (this is only a reference configuration; see Figure 4-3).
- **Basic Event:** Request to send an ATM_PDU in the equivalent-terminal.
- **Definition:** The SCR, and the BT denoted as of the ATM connection are defined by the GCRA(1/SCR, BT) based on the arrivals of the basic event defined above. The increment parameter of the GCRA is 1/SCR and BT is the limit parameter of the GCRA.

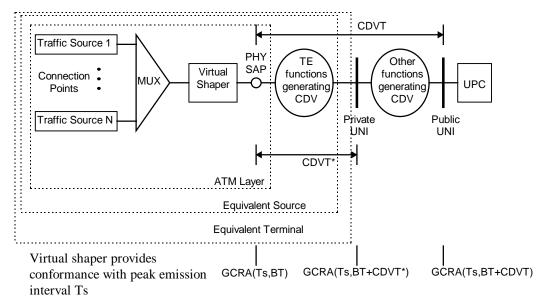

Figure 4-3: SCR and BT Reference Model

In the signaling message, the SCR is coded as cells per second. The granularity supported by the signaling message is 1 cell/s. The defined coding for the SCR in the signaling message does not imply that any UPC mechanism has to support the same linear granularity for the SCR across the complete defined cell rate range. An interpretation of the definition of SCR and BT in conjunction with PCR is given in Annex B.4.

4.4.4.3 CDVT

As shown in Figure 4-3, the CDVT is defined in relation to the SCR according to the GCRA. In particular, the CDVT at the public UNI, is defined in relation to the SCR according to the algorithm GCRA(T_s , BT+CDVT), where T_s is the inverse of SCR. Likewise, the CDVT* at the private UNI, is defined in relation to the SCR according to the algorithm GCRA(T_s , BT+CDVT*).

4.5 Traffic Contract and Conformance Definitions

The conformance of cells of a connection at an interface is defined in relation to the conformance algorithm and corresponding parameters specified in the connection traffic descriptor. This conformance definition is specified in the traffic contract. The set of conformance definitions that is supported at the public UNI is network specific. Future service categories may require the definition of new traffic contract parameters.

The ITU-T provides a definition of the granularity of PCR, SCR, CDVT, and BT used for defining conformance of a CBR or VBR connection, see ITU-T Recommendation I.371.

For network operations, there are two models for the CLP=1 cell flow:

- **CLP-transparent**: The network generally disregards the CLP bit. The CLR objective applies only to the aggregate CLP=0+1 cell flow, for which the CLP=1 cells experience the same CLR as the CLP=0 cells. The tagging option does not apply to this model (see Section 5.3.6).
- **CLP-significant**: The CLR objective applies only to the CLP=0 cell flow. The CLR for the CLP=1 flow is unspecified, as is the CLR for the aggregate flow (CLP=0+1). Network tagging applies as an option. The network may make a best-effort attempt to transmit the CLP=1 flow. In such a case, the network is likely to employ selective discard (but this will not count against the CLR objective of the connection).

For the conformance definitions listed below, the CLP-transparent model is used for CBR.1 and VBR.1, and the CLP-significant model is used for VBR.2, VBR.3, GFR.1 and GFR.2.

4.5.1 Traffic Contract and Conformance Definition for CBR Service

Conformance for a CBR connection is characterized by PCR and the corresponding CDVT for the CLP=0+1 traffic flow.

- (R) PCR for CLP=0+1 is a mandatory traffic parameter in any CBR source traffic descriptor.
- (**R**) For CBR SVCs, the PCR for CLP=0+1 shall be explicitly specified by the source for each direction in the initial connection establishment message.
- (R) The CDVT is a mandatory parameter in any CBR connection traffic descriptor.
- **(R)** The CDVT shall be either explicitly specified at subscription time or implicitly specified for any CBR connection.
- (**R**) For SVCs, the signaling message shall be capable of conveying information that identifies at least the following set of conformance definitions. For PVCs, the conformance definition shall be explicitly identified at subscription time.

4.5.1.1 CBR.1: Conformance Definition for PCR (CLP=0+1)

The following is a conformance definition for a source traffic descriptor that specifies PCR for the CLP=0+1 cell stream:

- 1. One GCRA(T_{0+1} , CDVT) defining the CDVT in relation to the PCR of the CLP=0+1 cell stream. T_{0+1} is the inverse of the PCR specified for the CLP=0+1 cell flow.
- 2. A cell that is conforming to the GCRA in (1) is said to be conforming to the connection traffic descriptor.

The tagging option is not applicable to this conformance definition since no separate rate is specified for CLP=0. The CLR objective applies to the aggregate CLP=0+1 cell stream.

4.5.2 Traffic Contract and Conformance Definition for rt-VBR and nrt-VBR

Conformance for a rt-VBR or nrt-VBR connection is characterized by an SCR parameter and corresponding MBS parameter for one or more traffic flows, in addition to a PCR parameter and corresponding CDVT for at least the CLP=0+1 flow. Real-time VBR and nrt-VBR are typically distinguished by their QoS parameters, but also by the magnitude(s) of the MBSs supported. Larger MBSs are more typical for nrt-VBR connections. The relationship between BT and MBS is given in Annex B.4.

- **(R)** PCR for CLP=0+1 is a mandatory traffic parameter in any source traffic descriptor for a rt-VBR or nrt-VBR connection.
- (**R**) For rt-VBR or nrt-VBR SVCs, the PCR for CLP=0+1 must be explicitly specified for each direction in the initial establishment message.
- (**R**) CDVT is a mandatory parameter in any connection traffic descriptor for a rt-VBR or nrt-VBR connection.
- (**R**) CDVT shall be either explicitly specified at subscription time or implicitly specified for any rt-VBR or nrt-VBR connection.
- **(R)** For SVCs, the signaling message shall be capable of conveying information that identifies at least the following set of conformance definitions. For permanent connections the conformance definition shall be explicitly identified at subscription time.

4.5.2.1 VBR.1: Conformance Definition for PCR (CLP=0+1) and SCR (CLP=0+1)

The following is a conformance definition for a source traffic descriptor that specifies PCR for the CLP=0+1 cell stream and SCR for the CLP=0+1 cell stream:

- 1. One GCRA(T_{0+1} , CDVT) defining the CDVT in relation to the PCR of the CLP=0+1 cell stream. T_{0+1} is the inverse of PCR (CLP=0+1).
- 2. One GCRA(T_{s0+1} , BT_{0+1} +CDVT) defining the sum of the CDVT and the BT in relation to the SCR of the CLP=0+1 cell stream. T_{s0+1} is the inverse of SCR (CLP=0+1).
- 3. A cell that is conforming to both GCRAs (1) and (2) above is said to be conforming to the connection traffic descriptor.

The tagging option is not applicable to this conformance definition. The CLR objective applies to the aggregate CLP=0+1 cell stream.

4.5.2.2 VBR.2: Conformance Definition for PCR (CLP=0+1) and SCR (CLP=0)

The following is a conformance definition for a source traffic descriptor that specifies PCR for the CLP=0+1 cell stream and SCR for the CLP=0 cell stream:

- 1. One GCRA(T_{0+1} , CDVT) defining the CDVT in relation to the PCR of the CLP=0+1 cell stream. T_{0+1} is the inverse of PCR (CLP=0+1).
- 2. One GCRA(T_{s0}, BT₀+CDVT) defining the sum of the CDVT and the BT in relation to the SCR of the CLP=0 cell stream. T_{s0} is the inverse of SCR (CLP=0).
- 3. A CLP=0 cell that is conforming to both GCRAs (1) and (2) above is said to be conforming to the connection traffic descriptor. A CLP=1 cell that is conforming to GCRA (1) above is said to be conforming to the connection traffic descriptor.

This conformance definition allows a connection to send CLP=1 cells at a PCR equal to the specified PCR of the CLP=0+1 cell stream. The CLR objective applies to the CLP=0 cell stream. The CLR of the CLP=1 cell-stream and the aggregate stream is undefined.

4.5.2.3 VBR.3: Conformance Definition for PCR (CLP=0+1) and SCR (CLP=0)

The following is a conformance definition for a source traffic descriptor that specifies PCR for the CLP=0+1 cell stream and SCR for the CLP=0 cell stream:

- 1. One GCRA(T_{0+1} , CDVT) defining the CDVT in relation to the PCR of the CLP=0+1 cell stream. T_{0+1} is the inverse of PCR (CLP=0+1).
- 2. One GCRA(T_{s0}, BT₀+CDVT) defining the sum of the CDVT and the BT in relation to the SCR of the CLP=0 cell stream. T_{s0} is the inverse of SCR (CLP=0).
- 3. A CLP=0 cell that is conforming to both GCRAs (1) and (2) above is said to be conforming to the connection traffic descriptor. A CLP=1 cell that is conforming to GCRA (1) above is said to be conforming to the connection traffic descriptor.
- 4. If the end-system requests tagging, and if tagging is supported by the network, a CLP=0 cell that is not conforming to GCRA (2) above, but is conforming to GCRA (1) above, will have its CLP bit changed to 1 and is said to be conforming to the connection traffic descriptor.

This conformance definition allows a connection to send CLP=1 cells at a PCR equal to the specified PCR of the CLP=0+1 cell stream. The CLR objective applies to the CLP=0 cell stream. The CLR of the CLP=1 cell-stream and the aggregate stream is undefined.

4.5.3 Traffic Contract and Conformance Definition for UBR Service

Conformance for a UBR connection is characterized by a single PCR and corresponding CDVT for the CLP=0+1 flow. The use of PCR for CAC, and enforcement of PCR by UPC, is network specific. However, if the user requests a non-zero minimum acceptable PCR that cannot be supported by the network, then the network may reject the call.

- **(R)** PCR for CLP=0+1 is a mandatory traffic parameter in any source traffic descriptor of a UBR connection.
- (R) The CDVT is a mandatory parameter in any connection traffic descriptor for a UBR connection.

- **(R)** The CDVT shall be either explicitly specified at subscription time or implicitly specified for a UBR connection.
- **(R)** For UBR SVCs, the PCR for CLP=0+1 shall be explicitly specified for each direction in the initial establishment message.

It is desirable that the source end-system conforms to PCR, but the enforcement of this is network specific.

4.5.3.1 UBR.1: Conformance definition for PCR (CLP=0+1), Tagging not applicable

The tagging option does not apply. The network shall not overwrite the CLP bit.

4.5.3.2 UBR.2: Conformance definition for PCR (CLP=0+1), Tagging applicable

The tagging option applies. The network may overwrite the CLP bit to 1 for any cell of that connection. However, such action does not necessarily imply a condition of non-conformance, as would be the case for other service categories.

4.5.4 Traffic Contract and Conformance Definition for ABR Service

The algorithm that defines conformance at an interface for each CLP=0 cell on a connection implicitly defines the response expected of the ABR end-system to feedback contained in backward RM-cells on the reverse connection. This feedback may include information in the Explicit Rate (ER) field or the Congestion Indication (CI) or No Increase (NI) bits of each backward RM-cell.

- (**R**) The ABR conformance definition is network specific, but must satisfy the following design constraints relative to parameters τ_1 , τ_2 , and τ_3 as specified for the connection, and delays t_1 and t_2 as defined in Section 4.5.4.1.
- 1. The conformance definition shall identify each CLP=0 cell as either conforming or non-conforming.
- 2. The conformance definition shall identify all CLP=0 cells on a connection conforming if all CLP=0 cells on a connection conform to $GCRA(MCR^{-1}, \tau_1)$.
- 3. The conformance definition used at an interface shall find a CLP=0 cell non-conforming only if its arrival time there and those of the preceding conforming CLP=0 cells on the connection could not have resulted from the ideal transmission times (as defined in Section 4.5.4.1) of an ABR source and delays t_1 and t_2 for the connection satisfying $\tau_3 \le t_2 \le \tau_2$ and $\max(t_1) \min(t_1) \le \tau_1$. In determining whether a CLP=0 cell is conforming, the network may assume that the inter-cell interval between that cell and the previous CLP=0 cell on the connection: (i) shall account for feedback conveyed in backward RM-cells transmitted across the interface on the backward connection more than τ_2 units before that previous CLP=0 cell, and (ii) shall not account for feedback conveyed in backward RM-cells transmitted across the interface on the backward connection less than τ_3 units before that previous CLP=0 cell.

The parameter τ_1 is the CDVT for the ABR connection. τ_2 and τ_3 are, respectively, the upper and lower bounds on the delay after which the rate change induced by a backward RM-cell departing from an interface (in the backward direction) is expected to be observed at the interface (in the forward direction).

An example of a conformance test satisfying (1)-(3) above is described in Appendix III and referred to as ER-conformance which is defined through the algorithm $DGCRA(MCR^{-1},PCR^{-1},ICR^{-1},\tau_p,\tau_2,\tau_3)$. ER-Conformance accounts only for feedback information conveyed in the ER field of the backward RM-cell and hence does not test whether the connection observes feedback conveyed in the CI or NI bits of the RM-cell. However, ER-conformance may be an adequate conformance definition for a network that does not rely on the CI or NI bits to convey feedback.

The minimal conformance definition for ABR is $GCRA(PCR^{-1}, \tau_1)$ where the PCR is defined for CLP=0 flow, according to Section 5.10 on ABR.

(O) The definitions of conformance and compliance optionally may be applied to the Private UNI or Private NNI.

4.5.4.1 Definitions of ABR Delays

The characteristics of traffic received at the private or public UNI on a given ABR connection depend critically on the delays between that interface and the source/destination (or virtual source/virtual destination) that generates the traffic. The delays most relevant to the characteristics of a flow received at the interface are defined relative to the transmission times of each CLP=0 cell by the traffic source. A transmission time for a CLP=0 cell is called an *Ideal Transmission Time (ITT)* if the difference between itself and the transmission time for the previous CLP=0 cell on the connection is greater than or equal to the minimum of (a) the inverse of the Available Cell Rate (ACR) in effect immediately after the transmission time of the first of the two cells and (b) the inverse of the ACR in effect immediately before the transmission time of the second of the two cells. The transmission time for the first cell on the connection is automatically an *ITT*. The ACR is calculated as specified in Section 5.10.4. The minimum is taken of (a) and (b) above, because an ABR source has the option of rescheduling the next cell to be transmitted on a connection when new feedback is received.

Two delays, t_1 and t_2 are particularly relevant to traffic characteristics at an interface. The delay t_1 denotes the time from a cell's transmission time by the traffic source to its receipt at the interface in question. The second delay t_1 denotes the sum of:

- the delay from the departure at the interface in question of a backward RM-cell on the backward connection to the receipt of the RM-cell by the traffic source, and
- the delay from the next transmission time for a CLP=0 cell on the connection (following the receipt of the RM-cell by the traffic source) to the arrival at the interface in question of that CLP=0 cell.

Hence, t_1 is the one-way transfer delay from the source to the interface and t_2 is the round-trip feedback delay between the interface and the source, excluding the residual of the inter-cell interval between successive transmission times.

4.5.5 Traffic Contract and Conformance Definition for GFR Service

The GFR service model includes the notions of conformance and service eligibility. The conformance for cells of a GFR connection is characterized by the PCR and the corresponding CDVT, the Maximum Frame Size (MFS) and consistent CLP bit values within a frame (see Section 4.5.5.1). The service guarantee applies to the number of cells defined as eligible for service (see Section 4.5.5.2).

- (**R**) PCR for CLP=0+1 is a mandatory traffic parameter in any source traffic descriptor of a GFR connection.
- (**R**) For GFR SVCs, the PCR for CLP=0+1 must be explicitly specified for each direction in the initial connection establishment message.
- (R) The CDVT is a mandatory parameter in any connection traffic descriptor for a GFR connection.
- (R) The CDVT shall be either explicitly specified at subscription time or implicitly specified for a GFR connection.
- (R) MFS is a mandatory traffic parameter in any source traffic descriptor of a GFR connection.
- (R) MCR for CLP=0 is a mandatory traffic parameter in any source traffic descriptor of a GFR connection.
- (R) MBS is a mandatory traffic parameter in any source traffic descriptor of a GFR connection.

There are two versions of GFR, GFR.1 and GFR.2. They differ with respect to the treatment of the CLP bit based on the F-GCRA (Frame-based Generic Cell Rate Algorithm) test (see Annex B.5):

• GFR.1: The CLP bit is transparently conveyed by the network. Tagging is not allowed.

• GFR.2: The CLP bit is not transparently conveyed by the network. Tagging is allowed.

4.5.5.1 Conformance

The GFR conformance definition is based on conformance of each cell of a frame with respect to the following conditions. A frame is conforming if all its cells are conforming, and is non-conforming if one or more of its cells are non-conforming.

A user generated cell is conforming if all of the following three conditions are met:

- The cell conforms to GCRA(1/PCR,CDVT), where PCR is defined for the CLP=0+1 cell stream.
- The CLP bit of the cell has the same value as the CLP bit of the first cell of the frame.
- The cell either is the last cell of the frame or the number of cells in the frame up to and including this cell is less than MFS.

The GCRA test is applied to every cell and the GCRA algorithm is thus updated for every cell that conforms to the GCRA test.

The conformance definition for a GFR cell is illustrated in Figure 4.4. The exact definition of conformance is indicated above. Figure 4.4 is for illustration purposes only.

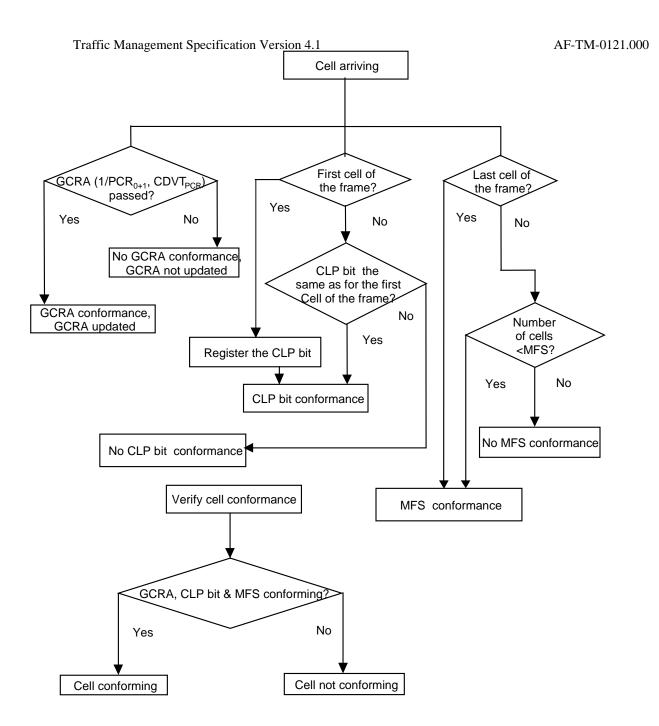

Figure 4-4: Illustration of GFR Cell Conformance Definition

4.5.5.2 Service Guarantee

The GFR service guarantee provides a low cell loss ratio for a number of cells, in complete CLP=0 frames, at least equal to the number of cells in eligible frames. A frame is eligible if and only if it meets both the following conditions:

- 1) it is conforming (see Section 4.5.5.1), and
- 2) it passes the F-GCRA(T,L) test of Annex B.5, with parameters T = 1/MCR and L = BT + CDVT.

All other frames are ineligible. Note that CLP=1 frames cannot pass the F-GCRA test, and therefore all CLP=1 frames are ineligible. In the case of connections containing only conforming frames, the F-GCRA(T,L) test can be replaced by the equivalent Simple-F-GCRA(T,L) test of Appendix VI.2.

The Burst Tolerance BT is defined as BT = (MBS-1)(1/MCR-1/PCR). The Maximum Burst Size MBS is expressed in units of cells and it shall be chosen to be greater than or equal to the quantity: 1 + [(MFS * PCR)/(PCR - MCR)]. PCR shall be strictly greater than MCR. The service guarantee is only applicable to GFR connections for which MCR > 0. A GFR connection may have MCR = 0, in which case there is no service guarantee (there are no eligible frames) and the F-GCRA test does not apply.

The network may discard or tag (if the user has allowed network tagging) all frames that are not eligible for the GFR service guarantee. An implementation that simply discards all frames that are not eligible would thus be compliant. However, it is expected that an implementation will attempt to deliver conforming traffic in excess of the F-GCRA constraint on the basis of available resources, with each GFR connection being provided at each link with a fair share of the local residual bandwidth. This specification does not attempt to define a criterion by which to determine if a given implementation meets the above expectation.

The network is allowed to discard any cell from an ineligible frame. It is recommended that the network not deliver an incomplete conforming frame. If an incomplete frame is delivered then the network should also attempt to deliver the last cell of that frame.

It is recommended that when the network cannot deliver all of a connection's ineligible frames then the network discards the connection's CLP=1 frames in preference to the same connection's ineligible CLP=0 frames

The conformance and F-GCRA tests are intended to allow the network to satisfy and the user to verify the GFR service guarantee. Neither users nor switch elements in the network are required to perform the F-GCRA test, although some implementations may rely on it to satisfy the GFR service guarantee. A network implementation of the F-GCRA may be less stringent than the F-GCRA definition in Annex B.5, for example with respect to the parameters T and L, and with respect to the conditions for updating the F-GCRA state for non-conforming cells. Similarly, no implementation of the three parts of the conformance test (Section 4.5.5.1) is required, and any implementation may be less stringent, for example with respect to the parameters of the GCRA, and with respect to the conditions for updating the GCRA when a frame is non-conforming for any reason.

Note that the GFR service guarantee is with respect to a certain number of cells (in complete CLP=0 frames). It is possible that a valid GFR implementation will provide service to an ineligible frame and then later deny service to an eligible frame. Due to the variable length nature of frames, when this event occurs it is possible that fewer cells will be serviced than were given the service guarantee. Such events are difficult to avoid, but are sufficiently rare that they are not inconsistent with the service guarantee. Appendix VI.3 explains this phenomenon in more detail and also (in Section VI.3.3) shows conditions under which an implementation can reduce the probability of such events to zero.

See Appendix VI.1 for a complete classification of frames in terms of marking/tagging, conformance and passing of the F-GCRA test.

4.5.5.3 Use of Tagging and Service Implications

In any GFR connection, frames of lesser importance may be marked by the source; such frames are not subject to the CLR objective. Tagging applies only when the GFR.2 conformance definition is used. Networks may tag frames (i.e. tag cells within frames) that are ineligible.

Any network element that sets the CLP bit of a cell to 1 shall set the CLP bit of every other cell of the same frame to 1 as well. No partial frame marking or tagging is allowed.

Compliance with this rule ensures that the GFR service guarantee can be supported even in the presence of network-based tagging. However it should be noted that network-based tagging may nevertheless affect to some extent the level of GFR service being provided, if tagging decisions are based simply on eligibility

criteria (e.g. if tagging decisions are determined by the outcome of the F-GCRA, independent of congestion conditions). Appendix VI.4 discusses possible implementation choices to support the GFR service category, and discusses the corresponding trade-offs in terms of complexity and performance.

4.5.6 Summary of Conformance Definitions

Table 4-1 summarizes the conformance definitions discussed in this section for the CBR, VBR, ABR, GFR and UBR service categories.

Conformance Definition	PCR flow	SCR flow	Tagging option active	MCR	CLR on
CBR.1	0 + 1	ns ₁	n/a ₂	ns	0+1
VBR.1	0 + 1	0 + 1	n/a	ns	0 + 1
VBR.2	0 + 1	0	No	ns	0
VBR.3	0 + 1	0	Yes	ns	0
ABR	0	ns	n/a	Yes	$0_{\scriptscriptstyle 6}$
GFR.1	0 + 1	ns	No	Yes	0,
GFR.2	0 + 1	ns	Yes ₅	Yes	0,
UBR.1	0 + 1	ns	No	ns	U_3
UBR.2	0 + 1	ns	Yes ₄	ns	U

Table 4-1: Summary of conformance definitions

Notes for Table 4-1:

- 1. ns means not specified.
- 2. n/a means that tagging is not applicable.
- 3. U means that CLR is unspecified (for both CLP=0 & CLP=1).
- 4. When the tagging option is used for a UBR connection the network may overwrite the CLP bit to 1 for any cell of that connection. However, such action does not necessarily imply a condition of non-conformance, as would be the case for other service categories.
- 5. Tagging is applicable to all cells of a frame that is deemed ineligible for the service guarantee. Tagging has to be applied uniformly in all cells of a frame.
- 6. CLR is low for sources that adjust cell flow in response to control information. Whether a quantitative value for CLR is specified is network specific.
- 7. CLR is low for frames that are eligible for the service guarantee. Whether a quantitative value for CLR is specified is network specific.

5. Functions and Procedures for Traffic Management

5.1 Introduction

Functions referred to as congestion control functions in this specification are intended to react to network congestion in order to minimize its intensity, spread and duration.

The following set of traffic and congestion control functions are described in this specification. ATM networks can implement one or a combination of these functions in order to meet QoS objectives of compliant connections.

- Connection Admission Control (Section 5.2)
- Usage Parameter Control (Section 5.3)
- Selective Cell Discard (Section 5.4)
- Traffic Shaping (Section 5.5)
- Explicit Forward Congestion Indication (Section 5.6)
- Resource Management using Virtual Paths (Section 5.7)
- Frame Discard (Section 5.8)
- Generic Flow Control (Section 5.9)
- ABR Flow Control (Section 5.10).

Different levels of network performance may be provided on connections by proper routing, traffic shaping, priority control and resource allocation to meet the required QoS for these connections.

5.2 Connection Admission Control

The Connection Admission Control (CAC) function is defined as the set of actions taken by the network at SVC establishment or by Network Management during PVC establishment in order to determine whether a connection can be progressed or should be rejected.

(R) The information contained in the traffic contract (Section 4) shall be accessible to the CAC function.

Based on the CAC function, a connection request is progressed only when sufficient resources are available at each successive network element to establish the connection through the whole network based on its service category, traffic contract, and QoS, and in order to maintain the agreed QoS of existing connections.

For each connection request, the CAC function shall be able to derive the following information from the traffic contract (see Section 4.2):

- Values of parameters in the source traffic descriptor (Section 4.1.2);
- Requested and acceptable values of each QoS parameter and the requested QoS class (Section 3);
- Value of the CDVT (Section 4.4.1);
- Requested conformance definition (Section 4.5).

The CAC function makes use of the traffic contract and the network's definition of a compliant connection to determine:

- whether the connection can be accepted or not;
- the connection traffic parameters (see Section 4.1.3) needed by usage parameter control (see Section 5.3.1);
- allocation of network resources.

Different strategies for network resource allocation may be applied for CLP=0 and CLP=1 traffic flows. In addition, information such as the measured network load may be used when performing the CAC function. This may allow a network to achieve higher network utilization while still meeting the network performance objectives.

The CAC function is network specific.

5.3 Usage Parameter Control

(O) The UPC function is optional at the UNI.

5.3.1 UPC Functions

Usage Parameter Control (UPC) is defined as the set of actions taken by the network to monitor traffic and enforce the traffic contract. Its main purpose is to protect network resources from malicious as well as unintentional misbehavior, which can affect the QoS of other established connections. This protection is achieved by detecting violations of negotiated parameters and taking appropriate actions.

Connection monitoring at a UNI (private or public) is referred to as UPC. Connection monitoring at an NNI (private or public) is referred to as NPC. UPC is used as a more generic term (includes NPC) unless otherwise specified. Connection monitoring encompasses all connections crossing the interface where UPC is used. UPC applies to both user connections and signaling channels. Methods for monitoring meta-signaling channels and OAM flows are for further study.

The monitoring task for UPC is performed for VCCs and VPCs, respectively, by the following two actions:

- checking the validity of VPI and VCI (i.e., whether or not VPI/VCI values are associated with active VCCs) and monitoring the traffic entering the network from active VCCs in order to ensure that parameters agreed upon are not violated;
- 2. checking the validity of VPI (i.e., whether or not VPI values are associated with active VPCs), and monitoring the traffic entering the network from active VPCs in order to ensure that parameters agreed upon are not violated.

5.3.2 UPC Requirements

A network's fundamental obligation is to support QoS commitments on compliant connections (see Section 4.3). This specification does not assume that a UPC function is always necessary to meet that obligation. However, it is likely that in many networks a UPC will be deployed as part of a strategy for meeting QoS commitments. Therefore, it is required that UPC functions be capable of enforcing the traffic contract. This specification includes a number of requirements for capabilities that must be included in a UPC function. Whether a network operator chooses to exercise these capabilities is network specific.

5.3.3 UPC Performance

When a traffic contract conformance violation occurs, policing actions performed on the cells sent in excess of the traffic contract are not to be included in the network performance degradation allocated to the UPC.

The CTD and the CDV introduced by the UPC are also part of the CTD and CDV allocated to the network.

A method to determine whether a traffic flow is conforming to a negotiated PCR at a given interface is defined for network performance purposes. Non-conformance is measurable by a 1-point measurement process in terms of the ratio γ_M between the number of cells exceeding the traffic contract and the total number of submitted cells.

An ideal UPC implementing the one-point measurement process would only take policing actions on a number of cells according to this ratio. Although the process allows for a cell-based decision, it is not possible to predict which particular cells of a connection with non-conforming cells will suffer from the policing action (because of measurement phasing).

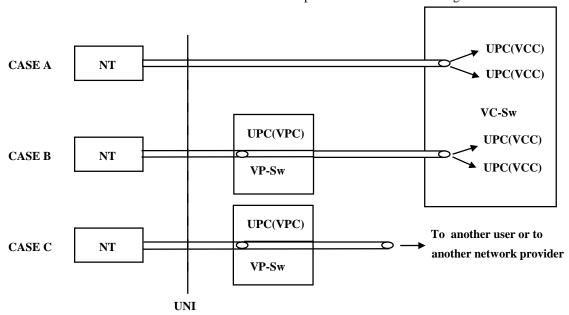

According to the definition of the conformance of a traffic flow to a PCR, the transparency of a UPC mechanism can be defined by the accuracy with which this mechanism approaches the ideal mechanism, i.e., the difference between the reference policing ratio γ_M and the actual policing ratio γ_P . A positive difference means that the UPC is taking less policing action than allowed. A negative difference means that policing actions are unduly taken by the UPC.

The above description also applies to the SCR and the MBS traffic parameters. The exact way of measuring the transparency of a given mechanism for the UPC and its dependence on time is for further study.

For further information on UPC/NPC accuracy and transparency see ITU-T Recommendation I.371.

5.3.4 UPC Location

It is recommended that UPC be performed at the points where the virtual path link or virtual channel link connected to the NT is terminated in the network. Three possibilities are shown in Figure 5-1.

NT: Network Termination

VC-Sw: Virtual Channel Switching Function VP-Sw: Virtual Path Switching Function

Figure 5-1: Location of the UPC Functions

Note: Provision of UPC at other locations is for further study.

In the following, VC-Sw stands for Virtual Channel Switching Function, and VP-Sw stands for Virtual Path Switching Function. The following VC-Sws and VP-Sws refer to the first switches on the network side of the UNI. A VC-Sw or a VP-Sw may respectively be a VCC or VPC concentrator.

If connected directly to a VC-Sw (CASE A of Figure 5-1), it is recommended that the UPC function be performed on VCCs within the VC-Sw before the switching function is executed (action 1, Section 5.3.1).

If connected directly to VC-Sw via VP-Sw (CASE B of Figure 5-1), it is recommended that the UPC function be performed on VPCs within the VP-Sw before the switching function is executed (action 2, Section 5.3.1) and on VCCs within the VC-Sw before the switching function is executed (action 1, Section 5.3.1).

If connected to an end-system or to another network via a VP-Sw (CASE C of Figure 5-1), it is recommended that the UPC function be performed on VPCs within the VP-Sw before the switching function is executed (action 2, Section 5.3.1).

In CASE C of Figure 5-1, the VCC usage parameter control may be done by the first network (if any) where a VC-Sw is present.

5.3.5 Traffic Parameters Subject to UPC Enforcement

The traffic parameters that may be subject to UPC enforcement are those included in the source traffic descriptor.

(**R**) The UPC function shall be capable of enforcing PCR for all connections.

This is a requirement on the capability of the UPC. When deploying a UPC, a network operator will usually configure the UPC to enforce PCR, but it is not required to do so.

5.3.6 UPC Actions (Cell Tagging and Discard)

The UPC is intended to ensure conformance by a connection with the negotiated traffic contract. At the cell level, actions of the UPC function may include:

- cell passing;
- cell tagging (network and user option); cell tagging operates on CLP=0 cells only, by overwriting the CLP bit to 1;
- cell discarding.

A cell tagging function exists that is optional for both the network and the user. If supported by the network, the user may select tagging when the connection is established. The availability of tagging depends on the conformance definition of the connection.

The following three requirements are requirements on the capability of the UPC. When deploying a UPC, a network operator will usually configure the UPC to take the indicated actions on all cells. The network operator is not required to do so, however, as long as it meets its QoS commitments.

- (R) The UPC function shall be capable of passing a cell it identifies as conforming to the connection traffic descriptor.
- (\mathbf{R}) The UPC function shall be capable of discarding a cell it identifies as non-conforming to the connection traffic descriptor.
- (**R**) If the tagging option is used for a connection, the UPC function shall be capable of converting a CLP=0 cell into a CLP=1 cell when the cell is identified by the UPC function as non-conforming to the CLP=0 cell stream.
- (**R**) If the tagging option is applied to the MCR objective of a GFR.2 connection, the corresponding UPC function shall be capable of converting all CLP=0 cells of a frame into CLP=1 cells when that frame is identified by the UPC function as not eligible according to the F-GCRA test of Annex B.5.

Those cells that have the CLP bit converted from '0' to '1' are called tagged cells. Tagging is used to transform a non-conforming CLP=0 cell into a conforming CLP=1 cell when the cell is conforming to the aggregate CLP=0+1 flow. If a CLP=0 cell is not conforming to the aggregate CLP=0+1 flow, tagging will not make it conforming. Therefore, the tagging option never applies to the aggregate CLP=0+1 flow, but applies to the CLP=0 flow.

(O) Following the UPC function, traffic shaping may be used to perform cell re-scheduling (e.g., to reduce cell clumping).

In addition to the above actions at the cell level, one other action performed at the connection level may optionally be initiated by the UPC.

(O) The UPC function may initiate the release of an identified non-compliant SVC.

5.3.7 Relationship between UPC, CLP, and Network Performance

For "CLP Significant" connections (see Section 4.5), network resources are allocated to CLP=0 and CLP=1 traffic flows as described in Section 5.2. By controlling the connection traffic flows, allocating adequate resources and selecting suitable routes, a network may provide the requested service category and QoS parameters for CLP=0 and CLP=0+1 cell flows.

When no additional network resource has been allocated for the CLP=1 traffic flow (either on user request or due to network provisioning), CLP=0 cells identified by the UPC as non-conforming may be discarded. In this case, tagging is not applicable.

Section 5.3.3 addresses undue UPC actions on compliant ATM connections. This is part of the network performance degradation allocated to the UPC and should occur with very low probability.

When cells of the aggregate CLP=0+1 flow are non-conforming to the parameters negotiated for the aggregate stream, the UPC function performed on the aggregate flow may discard CLP=0 cells that would not be considered in excess by the UPC function performed on the CLP=0 cell stream.

5.3.8 Relationship between UPC and OAM

For OAM cell flows across the UNI, the network may require the user to specify traffic parameters for the OAM traffic of an ATM connection. Regardless of whether an end-system explicitly or implicitly specifies the OAM cell stream, the network may police OAM cell flows separately from user data cell streams or may police OAM cell flows together with user data cell streams. However, neither UNI 3.1 nor UNI 4.0 signaling support indication of an OAM traffic descriptor. Traffic parameters for OAM cell flow across the UNI may be explicitly specified at subscription time, or implicitly by a default rule.

The function used to limit the OAM flow is determined by the network. The network may offer alternative limits from which the end-system may select. If the network polices the OAM cell flows together with user data cell flows, the UPC parameters are adjusted appropriately to accommodate the OAM flow.

5.3.9 Reaction to UPC Failures

Due to equipment faults (e.g., in UPC devices and/or other network elements) the controlled traffic characteristics at the UPC/NPC could be different from the values agreed to during the call set-up phase. To cope with these situations, specific procedures of the management plane should be designed (e.g., in order to isolate the faulty link).

5.4 Selective Cell Discard

- (O) A congested network element may selectively discard cells that meet either or both of the following conditions:
- a) cells that belong to a non-compliant ATM connection;
- b) cells that have CLP=1.

This is to protect the CLP=0 flow as much as possible. However, if CLP=1 cells are dropped from a compliant ATM connection it is expected that the CLR objective for the connection, as determined by its conformance definition, will be still met.

5.5 Traffic Shaping

Traffic shaping is a mechanism that alters the traffic characteristics of a stream of cells on a connection to achieve better network efficiency whilst meeting the QoS objectives, or to ensure conformance at a subsequent interface.

(R)Traffic shaping shall maintain cell sequence integrity on a connection.

Examples of traffic shaping are peak cell rate reduction, burst length limiting, reduction of CDV by suitably spacing cells in time, and cell scheduling policy. The 2-point CDV resulting from local actions taken to reduce the magnitude of downstream 1-point CDV are not considered an impairment.

The decision whether or not to implement traffic shaping, and if implemented the location where shaping is done, is network specific. As an example a network may choose to perform traffic shaping in conjunction with suitable UPC/NPC functions and/or virtual source/destination. As a consequence, any connection may be subject to traffic shaping.

The options available to the network include:

a) No shaping

• Dimension the network in order to accommodate any flow of conforming cells at the ingress whilst ensuring conformance at the egress without any shaping function.

b) Shaping

- Dimension and operate the network so that any flow of conforming cells at the ingress is
 conveyed by the network or network segment whilst meeting QoS objectives and apply output
 shaping to the traffic in order to meet conformance tests at the egress.
- Shape the traffic at the ingress of the network or network segment and allocate resources
 according to the traffic characteristics achieved by shaping, whilst meeting QoS objectives and
 subsequent conformance tests at the network or network segment egress.

Traffic shaping may also be used within the end-system to ensure that the cells generated by the source or at the UNI are conforming to the negotiated traffic contract as defined in Section 4.5.

5.6 Explicit Forward Congestion Indication (EFCI)

A network element in an impending congested state or a congested state may set an EFCI in the cell header so that this indication may be examined by the destination end-system. For example, the end-system may use this indication to implement a protocol that adaptively lowers the cell rate of the connection during congestion or impending congestion. A network element that is not in a congested state or an impending congested state will not modify the value of this indication. An impending congested state is the state when a network element is operating around its engineered capacity level.

Since the use of EFCI by the end-system is optional for CBR, rt-VBR, nrt-VBR, GFR, and UBR, the network should not rely on this mechanism to control congestion. For ABR and end-system behavior is specified in Section 5.10.

5.7 Resource Management using Virtual Paths

Virtual Paths are an important component of traffic control and resource management in ATM networks. With relation to traffic control, VPCs can be used to:

- simplify CAC;
- implement a form of priority control by segregating groups of virtual connections according to service category;
- efficiently distribute messages for the operation of traffic control schemes (for example to indicate congestion in the network by distributing a single message for all VCCs comprising a VPC);
- aggregate user-to-user services such that the UPC can be applied to the traffic aggregate.

VPCs also play a key role in resource management. By reserving capacity on VPCs, the processing required to establish individual VCCs is reduced. Individual VCCs can be established by making simple connection admission decisions at nodes where VPCs are terminated. Strategies for the reservation of capacity on VPCs will be determined by the trade-off between increased capacity costs and reduced control costs. These strategies are network specific.

The peer-to-peer network performance on a given VCC depends on the performances of the consecutive VPCs used by this VCC and on how it is handled at the VPC end-point. See Figure 5-2.

When VCCs within a VPC require a range of QoS, the VPC performance objective should be set suitably for the most demanding VCC carried. The impact on resource allocation is network specific.

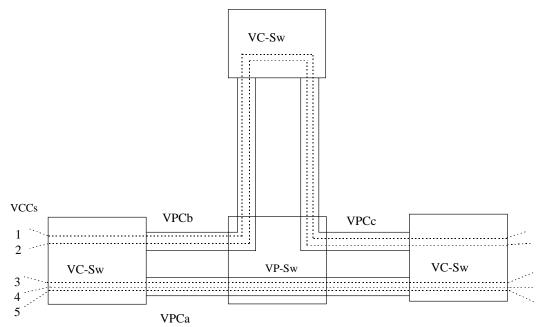

Figure 5-2: Mapping cell loss ratios for VCC and VPC

Figure 5-2 illustrates how the network performance offered on VCCs relates to the network performance offered by VPCs that support them. In the figure, VCCs 1 and 2 experience a network performance that depends on network performance on VPCs b and c and on how these VCCs are handled at the VPC end-points in the VC-Sw element. It may differ from network performance experienced by VCCs 3, 4 and 5, at least due to different network performances provided by VPCs.

VCCs 3, 4 and 5 experience similar network performances in terms of CTD and CDV if handled similarly at the VPC end-points in the VC-Sw element.

Section 3.2 of ITU-T Recommendation I.311 provides three applications of VPCs. These are:

- A) User-user application: the VPC extends between a pair of ATM end-systems
- B) User-network application: the VPC extends between a UNI and a network element
- C) Network-network application: the VPC extends between network elements.

The above cases imply:

In case A: because the network has no knowledge of the traffic contract, service category, and QoS of the VCCs within the VPC, it is the responsibility of the end-system to determine the appropriate service category and QoS parameters for the VPC in accordance with the network capabilities.

In cases B and C: the network is aware of the QoS of the VCCs carried within the VPC and has to accommodate them.

The relationship between the service category of the VPC and the service categories of the VCCs it carries is implementation specific.

Statistical multiplexing of VCCs within a VPC, where the aggregate peak cell rate of all VCCs may exceed the VPC capacity, is only possible when all VCCs within the VPC can tolerate the QoS that results from this statistical multiplexing. The way this is managed is network specific. As a consequence, when statistical multiplexing of Virtual Channel Links is applied by the network, VPCs may be used in order to separate traffic thereby preventing statistical multiplexing with other types of traffic. This requirement for separation implies that more than one VPC may be necessary between network origination/destination pairs to carry all of the service categories, traffic contract parameter values, and/or QoS parameter values supported by the network. See Section 5.10.9 for a discussion of ABR Virtual Paths.

5.8 Frame Discard

If a network element needs to discard cells, it is in many cases more effective to discard at the frame level rather than at the cell level. The term "frame" means the AAL protocol data unit. The network detects the frame boundaries by examining the SDU-type in the payload type field of the ATM cell header. Frame discard may be used whenever it is possible to delineate frame boundaries by examining the SDU-type in the payload type field of the ATM cell header. Frame discard may help avoid congestion collapse and can increase goodput.

In the case of GFR, frame discard is enabled. For service categories other than GFR, the network may invoke frame discard mechanisms only for connections for which it is specifically enabled, either via signaling or at subscription time.

The mechanism by which a network element decides to drop frames is implementation specific.

5.9 Generic Flow Control

The use of GFC at the UNI is neither assumed nor precluded in this specification. The GFC function is specified in ITU-T Recommendation I.150 and ITU-T Recommendation I.361.

5.10 ABR Flow Control

5.10.1 Introduction

In the ABR service, the source adapts its rate to changing network conditions. Information about the state of the network like bandwidth availability, state of congestion, and impending congestion, is conveyed to the source through special control cells called Resource Management Cells (RM-cells). The following sections specify the format and contents of the RM-cell, the source, destination, and switch behavior, and the parameters used in the service. Optional segmentation of networks, support for virtual paths, and a framework for point-to-multipoint behavior are also specified. For a description of the ABR flow control model, see Section 2.4.

5.10.2 ABR Service Parameters

This section defines the parameters which are used to implement ABR flow-control on a per-connection basis. All parameters are defined, including those that are actually constants and not altered by signaling.

5.10.2.1 Parameter Descriptions

Label	Description	Units and range
PCR	The Peak Cell Rate, PCR, is the cell rate that the source may never exceed.	In Cells/Sec, See Note 1 for range
MCR	The Minimum Cell Rate, MCR, is the rate at which the source is always allowed to send.	In Cells/Sec, See Note 1 for range
ICR	The Initial Cell Rate, ICR, is the rate at which a source should send initially and after an idle period.	In Cells/Sec, See Note 1 for range
RIF	Rate Increase Factor, RIF, controls the amount by which the cell transmission rate may increase upon receipt of an RM-cell.	RIF is a power of two, ranging from 1/32768 to 1.
Nrm	Nrm is the maximum number of cells a source may send for each forward RM-cell.	Power of 2 Range: 2 to 256
Mrm	Mrm controls allocation of bandwidth between forward RM-cells, backward RM-cells, and data cells.	Constant fixed at 2
RDF	The Rate Decrease Factor, RDF, controls the decrease in the cell transmission rate.	RDF is a power of 2 from 1/32,768 to 1
ACR	The Allowed Cell Rate, ACR, is the current rate at which a source is allowed to send.	Units: Cells/Sec
CRM	Missing RM-cell count. CRM limits the number of forward RM-cells that may be sent in the absence of received backward RM-cells.	CRM is an integer. Its size is implementation specific.
ADTF	The ACR Decrease Time Factor is the time permitted between sending RM-cells before the rate is decreased to ICR.	Units: seconds ADTF range: .01 to 10.23 sec: with granularity of 10 ms.
Trm	Trm provides an upper bound on the time between forward RM-cells for an active source.	Units: milliseconds Trm is 100 times a power of two Range: 100*2 ⁻⁷ to 100*2 ⁰
FRTT	The Fixed Round-Trip Time, FRTT, is the sum of the fixed and propagation delays from the source to a destination and back.	Units: 1 microseconds Range: 0 to 16.7 seconds
TBE	Transient Buffer Exposure, TBE, is the negotiated number of cells that the network would like to limit the source to sending during startup periods, before the first RM-cell returns.	Units: Cells Range: 0 to 16,777,215
CDF	The Cutoff Decrease Factor, CDF, controls the decrease in ACR associated with CRM.	CDF is zero, or a power of two in the range 1/64 to 1.
TCR	The Tagged Cell Rate, TCR, limits the rate at which a source may send out-of-rate forward RM-cells.	TCR is a constant fixed at 10 cells/second

Table 5-1: ABR parameter descriptions

Note 1: Rates are signaled as 24 bit integers that have a minimum value of zero, and a maximum value of 16,777,215. However, RM-cells use a 16-bit floating point format (see Section 5.10.3.2) that has a maximum value of 4,290,772,992.

5.10.2.2 Signaled Parameters

The following parameters are to be signaled and negotiated separately during connection establishment. If any parameter but PCR is unspecified by the source, the first switch will fill in the default value (before negotiation). MCR is optionally negotiable; if MCRmin is missing, then MCR is not negotiable.

Name	Negotiation	Default
PCR	down	mandatory
MCR	down to MCRmin if	0
	MCRmin is signaled, else no	
ICR	down	PCR
TBE	down	16,777,215
FRTT	accumulated	Note 1
RDF	Note 2	1/32,768
RIF	down	1

Table 5-2: Mandatory parameters to be signaled

Note 1: FRTT (Fixed Round-Trip Time) should be set by the source to the fixed source delay. FRTT is then accumulated during the call setup. FRTT is used to determine other parameters (see Section 5.10.2.4). It should be the sum of all the RM-cell fixed delays plus propagation delays in the round trip call path.

Note 2: The value of RDF may be increased or decreased, subject to the constraint that the ratio RDF / RIF shall not be decreased. (Hence, if RIF is decreased by a factor k, RDF may be decreased by at most a factor k, or it may be increased.)

Note: Some of the text on RDF negotiation in Section 6.5.2.3.6 of the PNNI V1.0 specification is obsolete.

5.10.2.3 Optionally Signaled Parameters

The following additional parameters can be optionally specified by the source during call setup but are optional for the source to specify. If not specified, the default value will be inserted upon call completion (without negotiation). Also, if any network element does not support Table 5-3, or a parameter in this group, the default value will be the value used.

Parameter	Negotiation	Default Value
Nrm	no	32
Trm	no	100
CDF	up	1/16
ADTF	down	0.5

Table 5-3: Optionally signaled ABR parameters

5.10.2.4 Parameter Computation After Call Setup

The following parameters are computed or updated by the forward and backward sources upon completion of the call setup when FRTT and the other parameters are known.

CRM CRM is computed as:

$$CRM = \left\lceil \frac{TBE}{Nrm} \right\rceil$$

where $\begin{bmatrix} x \end{bmatrix}$ is the smallest integer greater than or equal to x.

ICR ICR is updated after call setup is complete to insure TBE compliance as:

$$ICR = \max\left(MCR, \min\left(ICR, \frac{TBE}{FRTT}\right)\right)$$

5.10.3 RM-Cell Structure

Table 5-4 shows the fields and their position within the Resource Management (RM) cell format.

				Initial Value	
EIEI D	OCTET	DITT(-)	DESCRIPTION	.6	if switch-generated
FIELD	OCTET	BIT(s)	DESCRIPTION	if source-generated	or
					destination-generated
				RM-VPC: VCI=6 and P'	ΓI=110

	53	all			

Table 5-4: Fields and their position in RM-cells 8 7 6 5 4 3 2 1 DIR NI RA Res. BN CI Res. Res.

DIR = 0 for forward RM cells

= 1 for backward RM cells

BN = 1 for Non-Source Generated (BECN) RM cells

= 0 for Source Generated RM cells

CI = 1 to indicate congestion

= 0 otherwise

NI = 1 to indicate no additive increase allowed

= 0 otherwise

RA - Not used for ABR. See description below

Res. is an abbreviation for "Reserved"

Figure 5-3: Message Type Field (Octet 7)

5.10.3.1 Description of RM-cell Fields

This section describes how each field of the RM-cell is used. See Table 5-1 for requirements and options for initializing these fields. See also sections 5.10.5 through 5.10.7 for requirements and options for modifying the values in these fields.

• **Header:** The first five bytes of an RM-cell are the standard ATM header with PTI=110 (binary) for a VCC, and additionally VCI=6 for a VPC. The CLP bit is 0 if the RM-cell is in-rate and 1 if it is out-of-rate.

• **ID:** The protocol ID identifies the service using the RM-cell. The ITU has assigned protocol ID = 1 to ABR service.

Message Type Field

DIR: The DIR bit indicates which direction of data flow is associated with the RM-cell. A forward RM-cell, indicated by DIR=0, is associated with data cells flowing in the same direction. A backward RM-cell, indicated by DIR=1, is associated with data cells flowing in the opposite direction. DIR is changed from 0 to 1 when an RM-cell is turned around at a destination.

BN: The BN bit indicates whether the RM-cell is a Backward Explicit Congestion Notification (BECN) cell (i.e., non-source generated) or not. BN=0 indicates a source generated RM-cell while BN=1 indicates a BECN RM-cell generated by a destination or a switch.

CI: The CI (congestion indication) bit allows a network element to indicate that there is congestion in the network. When a source receives a backward RM-cell with CI=1 it decreases its ACR. When turning around a forward RM-cell, a destination will set CI=1 to indicate that the previous received data cell had the EFCI state set.

NI: The NI (no increase) bit is used to prevent a source from increasing its ACR. In contrast to CI=1, NI=1 does not require any decrease. A network element might set NI to 1 to indicate impending congestion. Normally, a source will initialize NI to 0 so that it might be allowed to increase its ACR, but it can indicate that it does not need a higher ACR by initializing NI to 1.

RA: The RA bit is not used for ATM Forum ABR.

- **ER:** The ER (Explicit Rate) field is used to limit the source ACR to a specific value. For each RM-cell ER is set by the source to a requested rate (such as PCR). It may be subsequently reduced by any network element in the path to a value that the element can sustain. ER is formatted as a rate as defined in Section 5.10.3.2.
- CCR: The CCR field is set by the source to its current ACR. It may be useful to network elements in computing a value to place in ER. For BECN cells, CCR=0. CCR is formatted as a rate as defined in Section 5.10.3.2.
- MCR: The MCR field carries the connection's Minimum Cell Rate. It may be useful to network elements in allocating bandwidth among connections. For BECN cells, MCR=0. MCR is formatted as a rate as defined in Section 5.10.3.2.
- **QL:** The QL field is not used for ATM Forum ABR.
- **SN:** The SN field is not used for ATM Forum ABR.
- **CRC-10:** The RM CRC is the same CRC used for all OAM cells. It is computed as the remainder of the division (modulo 2) by the generator polynomial of the product of x¹⁰ and the content of the RM-cell payload excluding the CRC field (374 bits). Each bit of this payload is considered as a coefficient (modulo 2) of a polynomial of degree 373 using the first bit as the coefficient of the highest order term. The CRC-10 generating polynomial is: 1+x +x⁴+x⁵+ x⁹+ x¹⁰. The result of the CRC calculation is placed with the least significant bit right justified in the CRC field. See ITU-T Recommendation I.610 for examples.

5.10.3.2 Rate Representation

Rates in the RM-cell and in the Source Behavior are represented in a binary floating point representation employing a 5 bit exponent, e, a 9 bit mantissa, m, and a 1 bit Nonzero flag, nz, as described below:

 $R=[2^e (1+m/512)]*nz$ cells/seconds where,

1 bit reserved	Bit 16, most significant bit of 16 bit field
$nz \in \{0,1\}$	Bit 15
	If $nz=0$ the rate is zero. If $nz=1$, the rate is as given
	by the fields e and m .
$0 \le e \le 31$	Bit 14 through bit 10. The exponent is a 5 bit unsigned integer.
$0 \le m \le 511$	Bit 9 through bit 1 The mantissa is a 9 bit unsigned integer.

This format is used to represent all rates used in the RM-cells and source behavior for ABR service. The bit positions of a floating point rate within a 16 bit word are given below:

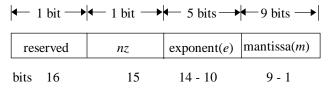

Figure 5-4: Rate format used in RM-cells

Note: Bits 16-9 are transmitted before bits 8-1 when using this encoding in the RM-cell.

5.10.3.3 In-rate and Out-of-rate Cell Types

ABR RM-cells shall be sent with CLP=0. ABR RM-cells with CLP=1 may be sent under the conditions explicitly stated in Sections 5.10.4, 5.10.5, and 5.10.6. All other ABR cells shall be sent with CLP=0. For ABR, CLP=0 cells are called "in-rate" cells, and CLP=1 cells are called "out-of-rate" cells. One use of out-of-rate RM-cells is to enable a rate increase for a connection that has an ACR of zero. The source would use the out-of-rate cells as probes to learn when it may increase its rate.

5.10.4 Source Behavior

The following items define the source behavior for CLP=0 and CLP=1 cell streams of a connection. By convention, the CLP=0 stream is referred to as in-rate, and the CLP=1 stream is referred to as out-of-rate. Data cells shall not be sent with CLP=1.

- The value of ACR shall never exceed PCR, nor shall it ever be less than MCR. The source shall never send in-rate cells at a rate exceeding ACR. The source may always send in-rate cells at a rate less than or equal to ACR.
- 2. Before a source sends the first cell after connection setup, it shall set ACR to at most ICR. The first in-rate cell sent shall be a forward RM-cell.
- 3. After the first in-rate forward RM-cell, in-rate cells shall be sent in the following order:
 - a) The next in-rate cell shall be a forward RM-cell if and only if, since the last in-rate forward RM-cell was sent, either:
 - i) at least Mrm in-rate cells have been sent and at least Trm time has elapsed, or
 - ii) Nrm-1 in-rate cells have been sent.
 - b) The next in-rate cell shall be a backward RM-cell if condition (a) above is not met, if a backward RM-cell is waiting for transmission, and if either:
 - i) no in-rate backward RM-cell has been sent since the last in-rate forward RM-cell, or
 - ii) no data cell is waiting for transmission.
 - c) The next in-rate cell sent shall be a data cell if neither condition (a) nor condition (b) above is met, and if a data cell is waiting for transmission.

- 4. Cells sent in accordance with source behaviors #1, #2, and #3 shall have CLP=0.
- 5. Before sending a forward in-rate RM-cell, if ACR > ICR and the time T that has elapsed since the last in-rate forward RM-cell was sent is greater than ADTF, then ACR shall be reduced to ICR.
- 6. Before sending an in-rate forward RM-cell, and after following behavior #5 above, if at least CRM in-rate forward RM-cells have been sent since the last backward RM-cell with BN=0 was received, then ACR shall be reduced by at least ACR*CDF, unless that reduction would result in a rate below MCR, in which case ACR shall be set to MCR.
- 7. After following behaviors #5 and #6 above, the ACR value shall be placed in the CCR field of the outgoing forward RM-cell, but only in-rate cells sent after the outgoing forward RM-cell need to follow the new rate.
- 8. When a backward RM-cell (in-rate or out-of-rate) is received with CI=1, then ACR shall be reduced by at least ACR*RDF, unless that reduction would result in a rate below MCR, in which case ACR shall be set to MCR. If the backward RM-cell has both CI=0 and NI=0, then the ACR may be increased by no more than RIF*PCR, to a rate not greater than PCR. If the backward RM-cell has NI=1, the ACR shall not be increased.
- 9. When a backward RM-cell (in-rate or out-of-rate) is received, and after ACR is adjusted according to source behavior #8, ACR is set to at most the minimum of ACR as computed in source behavior #8, and the ER field, but no lower than MCR.
- 10. When generating a forward RM-cell, the source shall assign values to the various RM-cell fields as specified for source-generated cells in Table 5-4.
- 11. Forward RM-cells may be sent out-of-rate (i.e., not conforming to the current ACR). Out-of-rate forward RM-cells shall not be sent at a rate greater than TCR.
- 12. A source shall reset EFCI on every data cell it sends.
- 13. The source may implement a use-it-or-lose it policy to reduce its ACR to a value that approximates the actual cell transmission rate. Use-it-or-lose-it policies are discussed in Appendix I.7.

Notes:

- 1. In-rate forward and backward RM-cells are included in the source rate allocated to a connection.
- 2. The source is responsible for handling local congestion within its scheduler in a fair manner. This congestion occurs when the sum of the rates to be scheduled exceeds the output rate of the scheduler. The method for handling local congestion is implementation specific.

5.10.5 Destination Behavior

The following items define the destination behavior for CLP=0 and CLP=1 cell streams of a connection. By convention, the CLP=0 stream is referred to as in-rate, and the CLP=1 stream is referred to as out-of-rate.

- 1. When a data cell is received, its EFCI indicator is saved as the EFCI state of the connection.
- 2. On receiving a forward RM-cell, the destination shall turn around the cell to return to the source. The DIR bit in the RM-cell shall be changed from "forward" to "backward", BN shall be set to zero, and the CCR, MCR, ER, CI, and NI fields in the RM-cell shall be unchanged except:
 - a) If the saved EFCI state is set, then the destination shall set CI=1 in the RM-cell, and the saved EFCI state shall be reset. It is preferred that this step is performed as close to the transmission time as possible;
 - b) The destination (having internal congestion) may reduce ER to whatever rate it can support and/or set CI=1 or NI=1. A destination shall either set the QL and SN fields to zero, preserve these fields, or set them in accordance with ITU-T Recommendation I.371.
 - The octets defined in Table 5-4 as reserved may be set to 6A (hexadecimal) or left unchanged.

The bits defined as reserved in Table 5-4 for octet 7 may be set to zero or left unchanged. The remaining fields shall be set in accordance with Section 5.10.3.1 (Note that this does not preclude looping fields back from the received RM-cell).

- 3. If a forward RM-cell is received by the destination while another turned-around RM-cell (on the same connection) is scheduled for in-rate transmission:
 - a) It is recommended that the contents of the old cell are overwritten by the contents of the new cell;
 - b) It is recommended that the old cell (after possibly having been over-written) shall be sent out-of-rate; alternatively the old cell may be discarded or remain scheduled for in-rate transmission;
 - c) It is required that the new cell be scheduled for in-rate transmission.
- 4. Regardless of the alternatives chosen in destination behavior #3 above, the contents of an older cell shall not be transmitted after the contents of a newer cell have been transmitted.
- 5. A destination may generate a backward RM-cell without having received a forward RM-cell. The rate of these backward RM-cells (including both in-rate and out-of-rate) shall be limited to 10 cells/second, per connection. When a destination generates an RM-cell it shall set either CI=1 or NI=1, shall set BN=1, and shall set the direction to backward. The destination shall assign values to the various RM-cell fields as specified for destination generated cells in Table 5-4.
- 6. When a forward RM-cell with CLP=1 is turned around it may be sent in-rate (with CLP=0) or out-of-rate (with CLP=1).

Notes:

- 1. "Turn around" designates a destination process of transmitting a backward RM-cell in response to having received a forward RM-cell.
- 2. It is recommended to turn around as many RM-cells as possible to minimize turn-around delay, first by using in-rate opportunities and then by using out-of-rate opportunities as available. Issues regarding turning RM-cells around are discussed in Appendix I.6.

5.10.6 Switch Behavior

The following items define the switch behavior for CLP=0 and CLP=1 cell streams of a connection. By convention, the CLP=0 stream is referred to as in-rate, and the CLP=1 stream is referred to as out-of-rate. Data cells shall not be sent with CLP=1.

- 1. A switch shall implement at least one of the following methods to control congestion at queuing points:
 - a) EFCI marking: The switch may set the EFCI state in the data cell headers;
 - b) Relative Rate Marking: The switch may set CI=1 or NI=1 in forward and/or backward RM-cells;
 - c) *Explicit Rate Marking:* The switch may reduce the ER field of forward and/or backward RM-cells;
 - d) *VS/VD Control*: The switch may segment the ABR control loop using a virtual source and destination.
- 2. A switch may generate a backward RM-cell. The rate of these backward RM-cells (including both in-rate and out-of-rate) shall be limited to 10 cells/second, per connection. When a switch generates an RM-cell it shall set either CI=1 or NI=1, shall set BN=1, and shall set the direction to backward. The switch shall assign values to the various RM-cell fields as specified for switch-generated cells in Table 5-4.
- 3. RM-cells may be transmitted out of sequence with respect to data cells. Sequence integrity within the RM-cell stream must be maintained.
- 4. For RM-cells that transit a switch (i.e., are received and then forwarded), the values of the various fields before the CRC-10 shall be unchanged except:
 - a) CI, NI, and ER may be modified as noted in #1 above

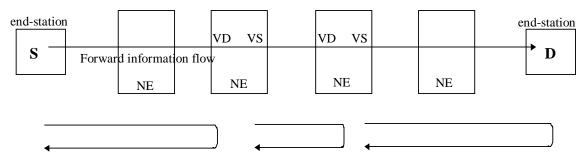

- b) RA, QL, and SN may be set in accordance with ITU-T Recommendation I.371
- c) MCR may be corrected to the connection's MCR if the incoming MCR value is incorrect.
- 5. The switch may implement a use-it-or-lose-it policy to reduce an ACR to a value that approximates the actual cell transmission rate from the source. Use-it-or-lose-it policies are discussed in Appendix I.7.

Notes:

- 1. A switch queuing point is a point of resource contention where cells may be potentially delayed or lost. A switch may contain multiple queuing points.
- 2. Some example switch mechanisms are presented in Appendix I.5.
- 3. The implications of combinations of the above methods is beyond the scope of this specification.

5.10.7 Virtual Source and Virtual Destination Behavior

VS/VD behavior divides an ABR connection into two or more separately controlled ABR segments. The coupling between adjacent ABR control segments associated with an ABR connection is implementation specific. Figure 5-5 illustrates an ABR virtual connection that incorporates segmentation.

Control loops associated with forward information flow

S: Source VS: Virtual Source D: Destination VD: Virtual Destination

NE: Network Element

Figure 5-5: Example of a segmented ABR virtual connection

The following applies to VS/VD behavior:

- 1. Each ABR control segment, except the first, is sourced by a virtual source. A virtual source assumes the behavior of an ABR source end point. Backward RM-cells received by a virtual source are removed from the connection.
- 2. Each ABR control segment, except the last, is terminated by a virtual destination. A virtual destination assumes the behavior of an ABR destination end point. Forward RM-cells received by a virtual destination shall be turned around as defined in destination behavior #2, and shall not be forwarded to the next segment of the connection.
- 3. The coupling between two adjacent ABR control segments associated with an ABR connection is implementation specific.
- 4. MCR shall be conveyed across VS/VD boundaries.
- 5. Setting of other parameters at VS/VD is network specific.

5.10.8 Point-to-Multipoint Behavior

The support of ABR point-to-multipoint connections is not required for ABR compliance as defined in this specification. However, the guidelines provided here are intended as a basic framework for a complete specification of point-to-multipoint ABR service in the future.

The operation of an ABR point-to-multipoint connection is functionally divided into behaviors for ABR sources/virtual sources, destinations/virtual destinations, switches, and branch points. According to their functional definitions, a source and destination is located at the root of the point-to-multipoint tree and at each of the leaves,

- one or more virtual sources/virtual destinations may be located on each branch of the tree,
- one or more switches may be located on each branch of the tree, and
- a branch-point is located at the intersection of two or more branches.

Note that switches, which determine the feedback sent from queuing points, are considered as functionally separate from branch points, which replicate cells traveling from root to leaves and consolidate feedback traveling from leaves to root. A branch is defined as any point-to-point segment of the point-to-multipoint tree. A branch may be classified as in the "non-responding state" if it has not transmitted (e.g., turned around) RM-cells towards the root for a time, the length of which is network specific but indicates the unavailability of the branch. Otherwise, the branch is in the "responding state." The classification of a branch as in the "non-responding state" is optional.

5.10.8.1 Behavior for Sources, Destinations, Switches, and VS/VDs of point-to-multipoint Connections

For a point-to-multipoint connection, the source behavior is the same as in Section 5.10.4, except that data cells shall not be transmitted in the direction from the leaves to the root. The destination behavior is the same as in Section 5.10.5, the switch behavior the same as in Section 5.10.6, and the virtual source/virtual destination behavior the same as in Section 5.10.7.

5.10.8.2 Behavior for Branch Points on Point-to-Multipoint Connections

- 1. An ABR branch point shall replicate each data cell and RM-cell received from the root onto each branch that leads to a leaf, whenever the branch is in the responding state. RM-cells may be transmitted onto the leaves out of sequence with respect to data cells, but the sequence integrity within the RM-cell stream transmitted to each branch must be preserved.
- 2. An ABR branch point shall transmit forward and backward RM-cells towards the root. This may be done by consolidating the information from forward and backward RM-cells received in the leaf-to-root direction from each branch in the responding state. However, a branch point is responsible for assuring that the ABR flow transmitted to each branch (both towards the leaves and towards the root) conforms to the expected behavior for a point-to-point ABR flow, given that the ABR flows received by the branch point do. There are network elements that support traditional multicasting (i.e., cell duplication) but cannot consolidate RM-cells. Their role within the framework of point-to-multipoint ABR service requires further study.

Branch points may send fewer RM-cells to the root than they receive from the leaves of a point-to-multipoint connection. The method of assigning values to the ER, CI, and NI fields is implementation specific. When a branch point sets the BN bit, it also sets either CI or NI.

- 3. An ABR branch point may:
 - buffer data and generate ABR feedback from queuing points as defined by the switch behavior in Section 5.10.6;
 - implement virtual sources and virtual destinations at one or more branches as defined in Section 5.10.6.

5.10.9 Support for Virtual Paths

This section clarifies three distinct configurations with respect to ABR VPC support:

1. Operation of ABR VCCs contained within a VPC

ABR VCCs within a VPC share its capacity, in the same way ABR connections share the capacity of a physical link. The method used to divide this VPC capacity among these VCCs is implementation specific.

2. Operation of an ABR VPC carrying VCCs

Figure 5-6 illustrates an ABR VPC, and shows that a VPC end-point occurs at a VC-Sw. Each end-point of an ABR VPC shall comply with the ABR source and destination behavior. In addition, each VC-Sw containing an ABR VPC end-point must satisfy the following two requirements whose purpose is to remove ambiguity about whether the EFCI state applies at the VCC or the VPC level.

(a) For every ABR VCC that is carried in the ABR VPC, the EFCI state of the most recent data cell shall be saved before that state is reset by the ABR VPC source. When a VCC-level backward RM-cell is forwarded by the VPC destination toward a VCC source, if the saved EFCI state for that VCC is set, then CI shall be set in the backward RM-cell and that saved EFCI state shall be reset. For non-ABR VCCs carried in the ABR VPC, the EFCI state need not be saved.

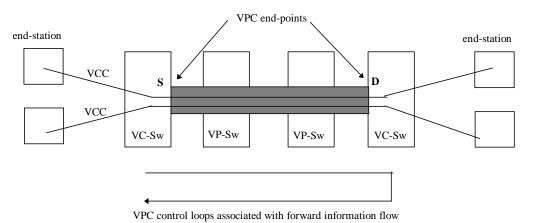

Figure 5-6: Example of an ABR VPC

Requirement (a) defines a VCC-level function. A VCC-level virtual destination is sufficient but not necessary to satisfy the requirement for one VCC.

(b) After saving the EFCI state as required in Destination Behavior #1, the VPC destination shall reset the EFCI state of any data cell it receives before it forwards the cell to the VCC portion of the VC-Sw containing the VPC end-point. Note that the VCC portion of the VC-Sw may indicate its own congestion state by setting the EFCI state of any data cell it forwards.

Requirements (a) and (b) need only be met by a VC-Sw implementing an actual ABR VPC source and destination. A network element that implements an ABR VPC virtual source or virtual destination need not satisfy requirements (a) and (b). Figure 5-7 illustrates an ABR VC-Sw containing an ABR VPC end-point that satisfies requirements (a) and (b).

RM-cells for VPC operation shall have VCI = 6 and PTI = 110 (binary). VCI 6 shall not have other functions assigned to it. This coding is used to distinguish the RM-cells controlling the VPC from any RM-

cells belonging to contained ABR VCCs. Switches operating at the VPC level on an ABR VPC shall only act on VPC RM-cells and shall ignore any VCC RM-cells within the VPC. On reception, all cells with VCI = 6 may be treated as VP RM-cells, even when the coding of the PTI field is not 110.

The method used by an ABR VPC end-point to allocate its dynamically changing capacity between the VCCs it contains is implementation specific. In particular, for an ABR VPC carrying ABR VCCs, the method used to couple control for the VCCs to bandwidth availability at the VPC end-point is implementation specific.

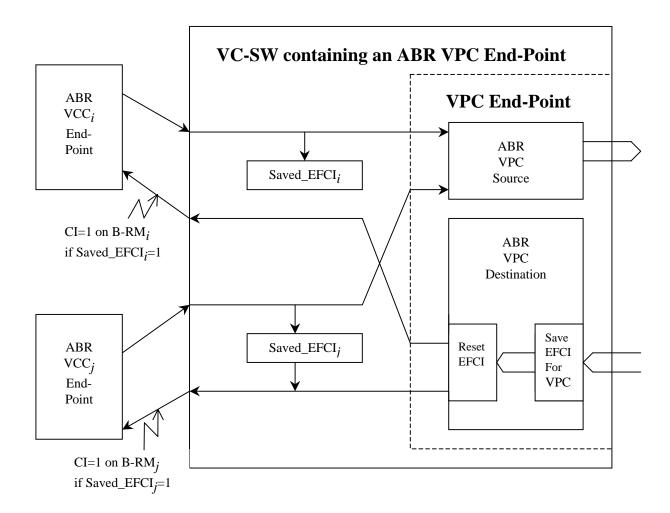

Figure 5-7: VC-Sw containing ABR VPC End-Point Satisfying Requirements (a) and (b)

3. Allocation of bandwidth between ABR VPCs and ABR VCCs on the same link

In the case where link capacity must be shared between both ABR-VPCs and ABR-VCCs the method used to allocate the bandwidth is implementation specific.

Normative Annex B: Traffic Contract Related Algorithms and Procedures

B.1 Equivalence of Virtual Scheduling and Continuous Leaky Bucket Algorithms

The virtual scheduling algorithm updates a Theoretical Arrival Time (TAT), that is the "nominal" arrival time of the cell assuming that the active source sends equally spaced cells. If the actual arrival time of a cell is not "too" early relative to the TAT, in particular if the actual arrival time is after TAT - L, then the cell is conforming, otherwise the cell is non-conforming.

Tracing the steps of the virtual scheduling algorithm in Figure B-1, at the arrival time of the first cell $t_a(1)$, the theoretical arrival time TAT is initialized to the current time, $t_a(1)$. For subsequent cells, if the arrival time of the k^{th} cell, $t_a(k)$, is actually after the current value of the TAT then the cell is conforming and TAT is updated to the current time $t_a(k)$, plus the increment I. If the arrival time of the k^{th} cell is greater than or equal to TAT - L but less than TAT (i.e., as expressed in Figure B-1, if TAT is less than or equal to $t_a(k)$ + L), then again the cell is conforming, and the TAT is increased by the increment I. Lastly, if the arrival time of the k^{th} cell is less than TAT-L (i.e., if TAT is greater than $t_a(k)$ + L), then the cell is non-conforming and the TAT is unchanged.

The continuous-state leaky bucket algorithm can be viewed as a finite-capacity bucket whose real-valued content drains out at a continuous rate of 1 unit of content per time-unit and whose content is increased by the increment I for each conforming cell. Equivalently, it can be viewed as the work load in a finite-capacity queue or as a real-valued counter. If, at a cell arrival, the content of the bucket is less than or equal to the limit value, L, then the cell is conforming, otherwise the cell is non-conforming. The capacity of the bucket (the upper bound on the counter) is L+I.

Tracing the steps of the continuous-state leaky bucket algorithm in Figure B-1 at the arrival time of the first cell $t_a(1)$, the content of bucket, X, is set to zero and the last conformance time (LCT) is set to $t_a(1)$. At the arrival time of the k^{th} cell, $t_a(k)$, first the content of the bucket is provisionally updated to the value X, that equals the content of the bucket, X, after the arrival of the last conforming cell minus the amount the bucket has drained since that arrival, where the content of the bucket is constrained to be non-negative. Second, if X is less than or equal to the limit value L, then the cell is conforming, and the bucket content X is set to X plus the increment X is set to the current cell, and the last conformance time X is set to the current time X.

If, on the other hand, X' is greater than the limit value L, then the cell is non-conforming and the values of X and LCT are not changed.

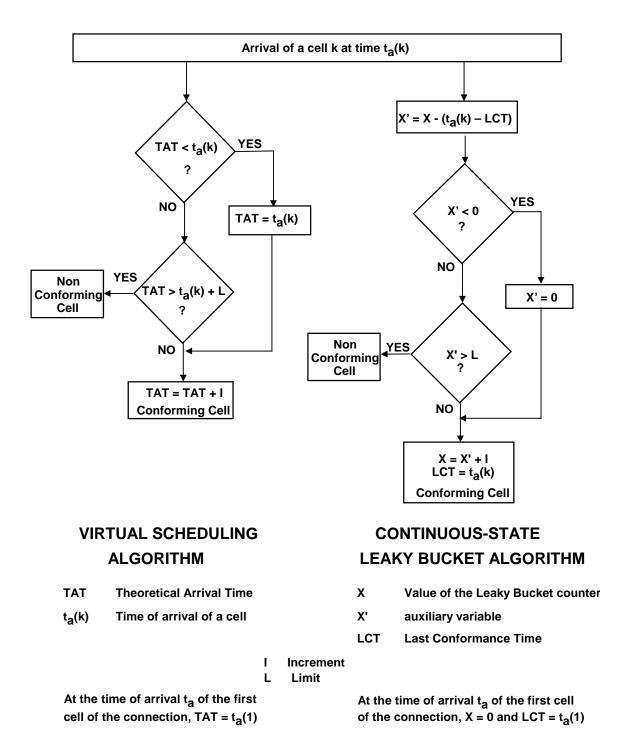

Figure B-1: Equivalent versions of the Generic Cell Rate Algorithm (same as Figure 4-1)

B.2 Interpretation of the Definition of PCR and Equivalent-Terminal

A "natural" or "intuitive" definition for PCR is the reciprocal of the minimum spacing of cells of an ATM connection on a transmission link. This intuitive definition is a rough approximation of the definition given in Section 4.4.3; however, this intuitive definition has technical flaws. These flaws are resolved by the Equivalent-Terminal definition of Section 4.4.3.1, at the possible expense of some obtuseness.

A simple technical flaw of the "intuitive" definition is that for a slotted transmission medium, it constrains the possible values of PCR to be the reciprocal of an integral number of cell slot times. For example and using round numbers, if 150Mb/s is provided to the ATM layer, then the next possible peak rate below 150Mb/s is 75Mb/s and the next possible one below that is 50Mb/s, and so on. This granularity is too coarse.

Note that the equivalent-terminal is a conceptual model (or reference configuration). The definition does not imply that the real Customer Premises Equipment must do the shaping. The shaping by the Equivalent-Terminal may be viewed as a "thought experiment". The fact that the source may not have shaped the traffic does not imply that the traffic is non-conforming since the criterion for conformance is at the UNI and is defined in terms of the GCRA.

Lastly, note that a definition of PCR does not tell the end-system the proper choice for the rate that meets the specific needs of the end-system. In particular, for VBR traffic sources, the equivalent-terminal model does not uniquely determine the value the end-system should pick for T. In the equivalent-terminal, T must be chosen so that the queue in the buffer ("mux") behind the shaper is stable. This allows T to be chosen so that its reciprocal is any value greater than the sustainable rate, up to the link rate.

B.3 Examples of Cell Clumping

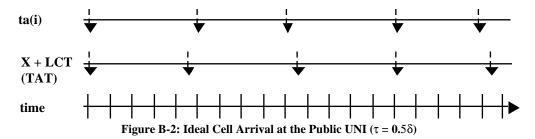

Figure B-2 through Figure B-5 show a few examples that illustrate the potential cell clumping allowed at the UNI for a given value of τ and for a given value of T (the inverse of the contracted PCR) of an ATM connection according to the $GCRA(T,\tau)$. In all these examples, it is assumed that $T=4.5\delta$, where δ is the time required to send 53 octets at the ATM layer data rate of 150 Mb/s (i.e., a peak bit rate of 33.3 Mb/s, including the cell header, is assumed). The notation in figures B-2 through B-5 is defined in Section 4.4.2, where it is noted that "X + LCT" equals "TAT" after the GCRA has been executed for each cell arrival.

From Figure B-2 it can be observed that the minimum value of τ to be accommodated at the UNI is 0.5 δ . From Figures B-3 to B-5, we observe that as τ increases, the minimum inter-arrival time between conforming cells decreases. When τ is greater than or equal to T - δ , the maximum number N of conforming back-to-back cells, i.e., at the full link rate, equals:

$$N = \left[1 + \frac{\tau}{T - \delta}\right]$$

for $T > \delta$, where $\lfloor x \rfloor$ stands for the integer part of x.

This result of back-to-back cell clumping is illustrated in Figure B-4 and Figure B-5.

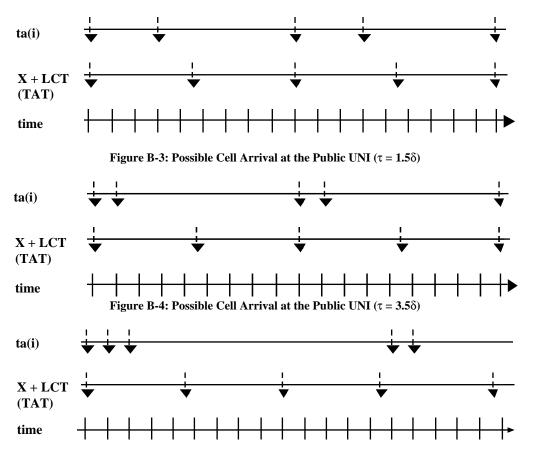

Figure B-5: Possible Cell Arrival at the Public UNI ($\tau = 7 \delta$)

B.4 Interpretation of SCR and BT in Conjunction with PCR

The SCR is an upper bound on the possible conforming "average rate" of an ATM connection, where "average rate" is the number of cells transmitted divided by the "duration of the connection"; where in this case, the "duration of the connection" is the time from the emission of the first cell until the state of the GCRA for the SCR returns to zero after the emission of the last cell of the connection. Relative to the PCR parameter, T_S is greater than T.

The SCR and BT traffic parameters enable the end-system to describe the future cell flow of an ATM connection in greater detail than just the PCR. If an end-system is able to specify the future cell flow in greater detail than just the PCR, then the network may be able to more efficiently utilize the network resources.

If the source wants to submit traffic that conforms to the SCR ($R_S = 1/T_S$) and the BT (τ_S) and the PCR (1/T) at the PHY-SAP of the equivalent-terminal, then it offers traffic that is conforming to the GCRA(T_S , τ_S) and the peak emission interval T (i.e., GCRA(T, 0)).

The BT together with the SCR and the GCRA determine the MBS that may be transmitted at the peak rate and still be in conformance with the GCRA(T_S , τ_S). The MBS in number of cells is given by

$$MBS = \left[1 + \frac{\tau_s}{T_s - T}\right]$$

where $\lfloor x \rfloor$ stands for the integer part of x.

In the signaling message, the BT may be conveyed through the MBS that is coded as a number of cells. The granularity supported by the signaling message is 1 cell. The MBS is used to derive the value of τ_S . The MBS and τ_S apply at the PHY_SAP of the equivalent-terminal. Note that in order to determine τ_S from the MBS, the PCR also needs to be specified. By convention, the peak rate used in the calculation of τ_S is the PCR of the CLP=0+1 cell flow. This convention holds whether τ_S is associated with the SCR for the CLP=0, or the CLP=1, or the CLP=0+1 cell flow of the connection. Also, given the MBS, T, and τ_S , then τ_S is not uniquely determined, but can be any value in the half-closed interval:

[
$$(MBS - 1)(T_S - T), MBS(T_S - T)$$
).

Hence, in order for all parties to derive a common value for τ_S , by convention, the minimum possible value is used. Thus, given the MBS, T, and T_S , then τ_S is set equal to:

$$\tau_{s} = (MBS - 1)(T_{s} - T)$$

Note that over any closed time interval of length t, the number of cells, N(t), that can be emitted with spacing no less than T and still be in conformance with $GCRA(T_S, \tau_S)$ is bounded by:

$$N(t) \le \min\left[\left[1 + \frac{t + \tau_s}{T_s}\right], \left[1 + \frac{t}{T}\right]\right)$$

Observe that if t is greater than or equal to the MBS * T, then the first term of the above equation applies; otherwise, the second term applies.

Note that the maximum conforming burst size, defined above, does not imply that bursts of this size with arbitrary spacing between the bursts would be conforming with the $GCRA(T_S, \tau_S)$. Rather, in order for a burst this large to be conforming, the cell stream needs to be idle long enough for the state of the GCRA associated with SCR to become zero (i.e., long enough for the continuous-state leaky bucket to become empty) prior to the burst.

If an end-system chooses to specify a value for the SCR and BT traffic parameters and wishes to emit conforming bursts at the peak rate, then the appropriate choice of T_S and τ_S depends on the minimum spacing between bursts as well as the burst size. For a cell flow of an ATM connection, if the minimum spacing between bursts at the equivalent-terminal is T_I and if the MBS (with inter-cell spacing T) is B, then the cell flow is conforming with GCRA(T_S , τ_S), if T_S , τ_S are chosen at least large enough to satisfy the following equation:

$$B = 1 + \left| \frac{\min(T_I - T_S, \tau_S)}{T_S - T} \right|$$

where $\lfloor x \rfloor$ stands for the integer part of x.

The traffic pattern conforming with the GCRA(T_S , τ_S) is in general not unique. Two traffic patterns are equivalent in relationship with the GCRA(T_S , τ_S) if they both conform at the PHY_SAP with the GCRA(T_S , τ_S) within the equivalent-terminal. Therefore, any cell stream that complies with the GCRA(T_S , 0) and GCRA(T_S , τ_S) at the PHY_SAP has a PCR = 1/T, a mean cell rate that is bounded by 1/ T_S and a burst length that is bounded by B. Note that the bounds 1/Ts and B are achievable. For example, a periodic cell stream with period B * T_S that transmits B cells at the peak rate with inter-burst spacing $T_I = B * (T_S - T) + T$ has PCR= 1/T, mean cell rate SCR=1/Ts and burst length B, and conforms to both GCRAs.

B.4.1 Relationship of CDVT, SCR and BT

ATM layer functions (e.g., cell multiplexing) may alter the characteristics of a connection's cell flow between the equivalent-terminal and the public or private UNI. Thus, as with the PCR, some tolerance for CDV may need to be considered in order that cells conforming to the GCRA(T_S , τ_S) at the equivalent-terminal are also conforming at the public UNI.

It can be shown that if an end-system emits cells such that the emission epochs are conforming with GCRA(T_s , τ_s), and if the cells pass through a customer premises ATM network that introduces a random delay within the interval [d_{min} , d_{max}], then all cells arriving at the public UNI are conforming with GCRA(T_s , τ_s + d_{max} - d_{min}). Thus if t, the CDVT parameter for the PCR is chosen to be d_{max} - d_{min} (or is chosen to be a small quantile, e.g., 10^{-9} , of the possible delay variation), then t could be used for the CDVT for the SCR as well. Note that although an end-system may choose to select the CDVT from the set of values supported by the network to be greater than or equal to d_{max} - d_{min} , there is no requirement to do so.

In analogy with the PCR, the criterion for conformance to the SCR and the BT is specified at the UNI (both public and private). At the public UNI, the criterion for conformance is specified in terms of GCRA with the arguments T_S and $\tau_S + \tau$, GCRA(T_S , $\tau_S + \tau$).

With regard to conformance to the SCR at the public UNI, note that conformance depends on τ_s and on τ only via their sum. Thus, the constraint of a common CDVT for both PCR and SCR is not unduly restrictive as an end-system still has freedom in the choice of τ_s (by the choice of MBS), and thus can choose τ_s so that $\tau_s + \tau$ has the desired value. However, note that a negative consequence of choosing τ_s dependent on τ is that it violates the modeling principle that traffic parameters in the source traffic descriptor are chosen based solely on the characteristics of the source and do not consider the equipment and traffic between the source and the UNI. For example, PCR is a traffic parameter, but CDVT is not a traffic parameter. Thus, although BT is defined herein as a traffic parameter, if the end-system chooses its value based on factors besides the source traffic, then the modeling principle for source traffic descriptors is violated.

Also note that to apply the equations for "MBS", "N(t)" and "B" in the previous section to burst sizes at the public UNI, as opposed to at the equivalent-terminal, one simply needs to replace the " τ_S " with " $\tau_S + \tau$."

The text in this section is also applicable to the private UNI, one simply needs to replace τ with τ^* .

B.5 Frame Based Generic Cell Rate Algorithm F-GCRA(T,L)

This Annex provides the reference algorithm that is used by the GFR service category to define QoS eligibility of a frame with respect to the negotiated value of a cell rate MCR = 1/T, assuming that a tolerance L is allowed. Refer to section 4.5.5.2 for details on how the F-GCRA is used in the context of GFR.

For connections containing only conforming frames, this algorithm is equivalent to the Simple F-GCRA(T,L) algorithm of Appendix VI.2.

Part 1: At the arrival of the first cell of a frame at time t_a at a given UNI or inter-network interface on the ATM connection:

```
X' := X - (ta- LPT)

if (X' > L) or (the cell has CLP=1) then
    passed := false
else
    passed := true
endif
```

Part 2: For all cells of frames whose first cell was a CLP=0 cell:

```
X' := X - (t_a - LPT)

X := max(0, X') + T

LPT := t_a
```

Part 3: If the cell is the last cell of a frame whose first cell was a CLP=0 cell:

```
if (frame is not conforming) or(passed) then
    X_1 := X
    LPT_1 := LPT
else
    X := X_1
    LPT := LPT_1
endif
```

In the above algorithm, X denotes the value of the Leaky Bucket Counter and LPT is the Last Pass Time. At the time of arrival t_a of the first cell of the connection to cross the given interface, X = 0 and LPT = t_a .

 X_1 and LPT_1 are the values of these parameters at the end of the last frame whose first cell was a CLP=0 cell. At the time of arrival t_a of the first cell of the connection to cross the given interface, $X_1 = 0$ and $LPT_1 = t_a$.

passed is a connection specific variable to store the status of a frame. It's initial value is irrelevant.

X' is an auxiliary variable.

Part 1 is executed before part 2, which is executed before part 3.

Note that F-GCRA(T,L) defines a minimum service guarantee. Actual implementations are allowed to use a simpler formulation that will offer better service than that specified by the F-GCRA. More precisely, they are not required to make the distinction between conforming and non-conforming frames. In particular, the algorithm Simple F-GCRA(T,L), as defined in Appendix VI.2, is also a valid implementation of the service guarantee for a connection that has no non-conforming frames.

Informative Appendix I: Implementation Examples on ABR Service Category

I.1 Example End-System Pseudocode

The following pseudocode provides an example of conforming behavior for the source end system (SES) and destination end system (DES). It represents a minimal but complete implementation of the specified end system behavior. This pseudocode also applies to the virtual source and virtual destination behaviors, as when segmented rate control is used by an intermediate network. This pseudocode example is provided for a single source connection. It assumes, but does not detail, a cell scheduler mechanism that controls the cell emissions from the SES. For simplicity of example, it also assumes that only out-of-rate forward RM-cells will be sent when ACR < TCR.

The behavior of the SES is controlled by the values assigned to a set of parameters. PCR, MCR, and ICR, are in units of cells per unit time, and RIF is dimensionless. RDF, CDF and Nrm are dimensionless. PCR and MCR are agreed upon at connection setup time. ICR, RIF, RDF, CDF and Nrm are established by the network(s) at connection setup time, with values that are determined to best optimize performance over various network trade-offs. Values for these parameters observe the following constraints:

```
MCR <= ICR <= PCR
MCR <= ACR <= PCR
0 <= CCR <= min (ACR, LCR)
```

where CCR is the current cell rate, reflecting the user's offered traffic. Generally, but not necessarily, CCR will equal either ACR or 0, as the source either has or doesn't have traffic to send. LCR is the cell rate due to the physical line limitation. In this pseudocode the parameter "MCR" may be utilized to represent:

- a) A Network Interface Card implementation limit, due to a lower bound on the integer precision, e.g., 1 cell/second,
- b) A (low) value gratuitously offered by the network to provide improved performance, or
- c) A means to support a contracted or guaranteed "MCR".

Each of the following parameters is assigned a value as a result of connection setup:

```
ICR, PCR, MCR, RIF, RDF, Nrm, Mrm, CRM, CDF, Trm, TCR, and ADTF.
```

In this section a "!" to the right of a pseudocode statement is the start of a comment. In the comments, "Sn" refers to source behavior #n, and "Dm" refers to destination behavior #m. Each connection has a few variables for its operation:

SES Variables (Per connection)

ACR Allowed Cell Rate

count Number of cells sent (all kinds) since the last forward RM-cell unack Number of forward RM-cells sent without an RM received

time-to-send The time scheduled to send the next cell (in-rate)
last-RM The time that the most recent RM was sent
turn-around A flag indicating there is an RM-cell to turn-around

first-turn A flag indicating the (first) turn-around RM has priority over data cells

CI-VC A flag indicating the EFCI bit was set on the previous data cell

Per-connection Initialization

ACR = ICR count = Nrm CI-VC = unack = 0 last-RM = now - Nrm/ICR

turn-around = false first-turn = true

TDF = TDFF/RDF * 2^Round-up[log2(PCR)]

End-System Pseudocode - Send

```
if cell-enters-empty-queue-event
                                                              ! external event
   if time-to-send not scheduled
       schedule: time-to-send = now
                                                              ! activate scheduler
if now >= time-to-send and
                                                              ! scheduled event
        (data-in-queue or turn-around)
                                                              ! something to send?
   if ACR < TCR
                      ! ACR is low: send only FRMs out-of-rate at TCR
       send RM(DIR=forward, CCR=ACR, ER=PCR, CI=0, NI=0, CLP=1)
                                                                   ! S11 (out-of-rate)
       schedule: time-to-send = now + 1/TCR
    else {
                      ! ACR >= TCR: send RM/data cells in-rate
                                                                              ! S3a

                                                                  ! D2: turn it around
     if turn-around
                                                                !S12(optional behavior)
          CI-TA = CI-TA \text{ or } CI-VC
          send RM(DIR=backward, CCR-TA, ER-TA, MCR-TA, CI-TA, NI-TA, CLP=1)
     CCR-TA= CCR; ER-TA= ER; MCR-TA= MCR; CI-TA= CI; NI-TA= NI
                                                                                  ! D3
     turn-around = true
     if time-to-send not scheduled
                                                             ! D2 (required behavior)
                                                             ! activate scheduler
          schedule: time-to-send = now
```

Note 1: These two code lines represent optional behavior wherein a scheduled cell may be rescheduled to take advantage of an increase in ACR.

The ABR conformance definition in Section 4.5.4 includes tolerances τ_1 , τ_2 , and τ_3 to departures from the idealized ABR behavior in which successive cells from a connection are always spaced at intervals 1/ACR and the forward cell flow is instantaneously affected by backward feedback. Below is an example of the first stage of a two-stage scheduler, where the first stage determines the earliest cell compliance time at the interface to the ABR source/destination that is consistent with a tolerance of TOL and the second stage resolves local congestion due to contention for bandwidth at this interface. It is consistent with the ABR conformance definition from Section 4.5.4 when the parameter τ_1 for the interface to the ABR source destination exceeds the sum of TOL and the variable delay (if any) at the second stage of the scheduler for the forward connection. The parameter TOL is implementation specific but should not exceed TBE/PCR.

```
(begin pseudocode)
```

```
TAT=now !initialize Theoretical Arrival Time
```

last_rm=now-Nrm/ICR

```
enqueue cell
schedule: time_to_send=max(TAT, now)
```

```
if now >= time_to_send
```

while (cell_in_queue and now >= TAT - TOL)

- (A) set virtual_time = max (TAT, now)
- (B) determine the type of cell to be sent (forward RM, backward RM, or data) by applying source behavior #3 as if the current time were equal to virtual_time and the time when the previous forward RM-cell was sent were equal to last_RM.
- (C) if the cell to be sent is a forward RM-cell,

(i) determine whether a decrease in the ACR is required by applying source behaviors #5 and #6 as if the current time were equal to virtual_time and the time when the previous forward RM-cell was sent were equal to last_rm.

(ii) set last_rm=virtual_time

(D) update ACR if necessary as specified by source behavior #7 and send the cell as specified by source behaviors #4, #7, #10, and #12 to the second stage of the scheduler.

(E) TAT =virtual_time + 1/ACR
if (cell_in_queue)
schedule: time_to_send= TAT

else

schedule: time_to_send=INFINITY

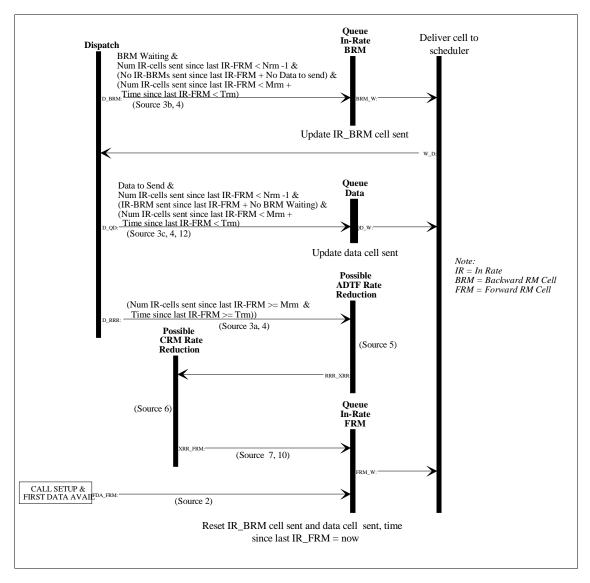

if receive RM(DIR=backward, CCR, ER, CI, NI, BN)
update ACR following source behaviors #8 and #9.

(end pseudocode)

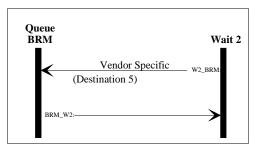

When TOL=0, the above is equivalent to the ideal source behavior in Section 5.10.4 for sending in-rate cells. If TOL>0, then the "while" loop in the above is entered at most once every TOL units of time, as long as cells are in queue. The while loop thus schedules cells in batches, where these batches are separated by a time TOL as long as there are cells to send. One result is that backward RM-cells will change the ACR only during the intervals between these batches. This introduces a lag of up to TOL from when a backward RM-cell is received by the source/destination to when the information in this backward RM-cells affects the scheduling. This lag is consistent with having $\tau_2 > \text{TOL}$.

I.2 State Machine

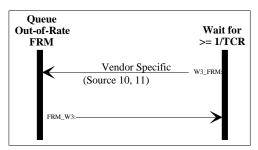

The four ABR service model State Machines are shown below. State Machine 1 controls the generation of Data cells as well as in-rate forward and backward RM-cells. This State Machine follows all of the behaviors specified in Sections 5.10.4 and 5.10.5. State machines 2 and 3 show the non-standard generation of RM-cells. The exact implementation of these state machines is implementation specific. Forward out-of-rate RM-cells are limited only by TCR. Backward RM-cells are limited by Destination behavior #5 (10 cells/seconds) and the number of forward RM-cells received. State machine 4 controls operation during reception of backward RM-cells. It should be noted that the Source and Destination textual behavior descriptions should take precedence in case of discrepancy.

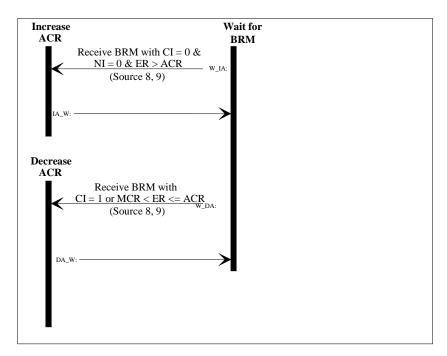

Generation of In-Rate Cells (Data, Forward and Backward RM-(State Machine #1)

Destination Generated Backward RM (BN=1) (State Machine #2)

Source Out-of-Rate Forward RM Generation (State Machine #3)

Backward RM Reception (State Machine #4)

I.3 Example Fairness Criteria

Define the following parameters:

- A = Total available bandwidth for all ABR connections on a given link.
- U = Sum of bandwidth of connections bottlenecked elsewhere (including those limited by PCR).
- B = A-U, bandwidth to be shared by connections bottlenecked on this link.
- N = Total number of active connections.
- N' = Number of active connections bottlenecked elsewhere.
- n = N-N', number of active connections bottlenecked on this link.
- M = Sum of MCRs of active connections within**n**.
- B(i) = Fair allocation for connection **i**.
- MCR(i) = MCR of connection **i**.

The following are the example fairness criteria for the given link.

1. Max-Min

The available bandwidth B is equally shared among n connections that are bottlenecked at the link.

B(i)=B/n.

Comments: This criterion only applies to the case where all connections are unweighted (or equally weighted) and with zero-MCR.

2. MCR plus equal share

The bandwidth allocation for a connection is its MCR plus equal share of the bandwidth B with used MCR removed.

B(i)=MCR(i)+(B-M)/n.

Comments: The criterion converges to Max-Min criteria as all MCRs approach zero. To achieve this criterion, the switch may need to use ACR-MCR to compute the fair share.

3. Maximum of MCR or Max-Min share

The bandwidth allocation for a connection is its MCR or Max-Min share, whichever is larger. B(i)=max(MCR(i), Max-Min share).

Comments: This criterion also converges to Max-Min criterion as all MCRs approach zero. The bandwidth allocation according to this criterion may need long iteration time to converge to the equilibrium point.

4. Allocation proportional to MCR

The bandwidth allocation for a connection is weighted proportional to its MCR. B(i)=B*(MCR(i)/M).

Comments: This criterion does not apply if there are connections with zero MCR.

5. Weighted allocation

The bandwidth allocation for connection i is proportional to its pre-determined weight, w(i). $B(i)=B*(w(i)/sum\ w(j))$.

Comments: The Max-Min criterion is a special case with all connections having equal weight.

The weight may be defined independent of MCR or dependent on MCR (e.g., option 4 is with weight proportional to MCR).

6. MCR plus weighted share

The bandwidth allocation for a connection is its MCR plus a weighted share of the bandwidth B with used MCRs removed.

$$B(i) = MCR(i) + (B - M) * (w(i)/sum w(j))$$

Comments: Max-Min, MCR plus equal share, and Allocation proportional to MCR are special cases. The weights may be defined independent of MCR or dependent on MCR.

I.4 MCR characteristics

This appendix provides a rationale for MCR, and explains its implications on networks and applications. Also see the pseudocode (Appendix I.1, above) for an implementation example.

Field of application

In the ABR service category, the ACR available to the application varies with network load. There may be some value of ACR below which the performance of the application degenerates. For example,

- protocol liveness may require that protocol control information be sent at some minimum rate;
- some applications may become intolerable to users if they are unable to send at least at some minimum rate;
- applications that need to run to completion within a period of time (e.g., an overnight disk backup that has to be completed by morning), will miss their deadline if they cannot transmit at least at some minimum rate.

For such applications, the concept of MCR is defined.

Some applications will have no way to determine an appropriate value of MCR, and MCR will not always be needed or wanted by applications or users. In particular, networks may have economic, administrative or other disincentives to specifying an MCR greater than 0.

The Internet concept of an elastic service does not include a MCR. The ABR service category is intended to meet the requirements of the elastic service definition when MCR=0.

In some applications, it may be possible for users to control MCR, even if an MCR is not inherent in the design of the application.

Definition of MCR

Minimum Cell Rate (MCR) is a rate negotiated between the end-systems and the network(s), such that the actual cell rate sent by the end-system on the ABR connection need never be less than MCR. MCR is negotiated independently for both directions of transfer on a bi-directional ATM connection.

MCR is negotiated between the end-systems and the network(s) using the connection control signaling procedures. The MCR agreed between the end-systems and the network(s) carrying the connection may range from 0 to the maximum value supported by the network(s). This maximum may be 0. If the calling end-system does not indicate a requested MCR, the default value of MCR is 0.

In the negotiation procedures specified in the signaling protocol, the calling end-system specifies a "requested MCR" and a "smallest acceptable MCR" (MCRmin of Section 5.10.2.2). The MCR value indicated when the connection is offered to the called end-system(s) will be either the "requested MCR", or, if that value is not available, a value between the "requested MCR" and the "smallest acceptable MCR". If the network(s) cannot offer at least the "smallest acceptable MCR", the connection attempt is blocked. Thus, by specifying a "smallest acceptable MCR" greater than 0 (i.e., a "floor" on the negotiation), the calling end-system accepts a risk that the connection will be blocked. Blocking in preference to unacceptable performance may be preferred by some applications and/or users.

The option of negotiating an MCR does not imply that ABR is intended to be a real-time service.

If an MCR > 0 is negotiated for the connection, the end-systems may transmit at any rate up to the greater of MCR and ACR. There is no obligation that end-systems transmit at a rate of at least MCR.

Implications for network resource allocation

Policy for resource allocation within networks and network elements is implementation specific subject to the constraint that these policies not preclude the network from meeting the ABR service objectives. Specifically, end-systems are not to be expected to reduce their ACR to less than MCR in order to meet the cell loss ratio objective.

Implications on connection admission control (CAC) and routing

Networks and network elements that offer MCR>0 need to incorporate reservation of MCR resources into their CAC functions in order to meet ABR service objectives. This implies blocking of connection attempts when the "smallest acceptable MCR" is greater than the resources that the network or network element can reserve for MCR.

During a connection establishment attempt for a connection that does not request MCR, or for which "smallest acceptable MCR" = 0, the CAC function will not block the connection attempt because of bandwidth (including MCR) allocated to other connections. Blocking due to CAC for other reasons is not precluded.

I.5 Example Switch Mechanisms

The following is a high level description of the switch mechanisms that were considered and in some cases simulated by various members of the traffic management working group. While general comments can be made about the relative merits of these various mechanisms detailed performance characteristics depend on the exact source and destination behavior used. The various switch mechanisms can be classified broadly depending on the congestion monitoring criteria used and the feedback mechanism employed. The feedback mechanisms have been typically either binary or calculating the explicit rate and sending this information to the source through the RM-cell.

I.5.1 Binary Feedback Schemes

The switches perform two important functions: a) Detect incipient congestion and b) provide binary feedback to the source. The simplest example of a binary feedback mechanism is based on the old DECbit

scheme and was described as part of the original proposal for an end-to-end rate based traffic control scheme. In this scheme all the connections share a common FIFO and the queue length is monitored by setting a threshold T. When the queue length exceeds the threshold congestion is declared and the cells passing through the queue have their EFCI bit set. When the queue length falls below the threshold the cells are passed without their EFCI bits set. In variations of this mechanism two thresholds can be used, a high threshold THigh, and a low threshold TLow. Typically as the queue increases past the low threshold and crosses the high threshold, THigh, congestion is declared and the cells passing through the queue have their EFCI bits set. When the queue starts emptying, the condition of congestion is not removed until the queue falls below the low threshold.

Binary feedback schemes where all the connections may share a common FIFO may sometimes suffer from unfairness problems depending on the network topology and the source and destination behavior employed. Given the same level of congestion at all the switches connections traveling more hops have a higher probability of having their EFCI bits set than those traveling a smaller number of hops. Depending on the source and destination behavior employed these long hop connections get very few opportunities to increase their rate and consequently their throughputs are starved giving rise to what has been called the "beat down problem".

Potential unfairness problems in binary feedback schemes where all the connections share a common FIFO can be alleviated by some enhancements to the basic scheme. The simplest enhancement is to provide separate FIFOs for each connection or groups of connections. This generally results in ensuring fairness among different connections. Another enhancement is to provide selective feedback or intelligent marking. In this scheme a switch computes a "fair share" and if congested sets EFCI bits in cells belonging to only those connections whose current rates are above the fair share. Examples of ways that a switch can compute the "fair share" are presented in the following sections on explicit rate feedback.

I.5.2 Explicit Rate Feedback Schemes

The switches perform three important functions:

- 1. Compute the fair share of the bandwidth for a connection that can be supported.
- 2. Determine the load. (e.g., This can be done by either monitoring the queue length or the queue growth rate).
- 3. Determine the actual explicit rate and send this information to the source.

Examples of explicit rate switch mechanisms are the Enhanced Proportional Rate Control Algorithm (EPRCA) and two congestion avoidance algorithms.

Note: some of the following ER switch mechanisms assume that the information in the forward RM-cell is correct. If the sources are not well behaving (e.g., they insert incorrect information) or the flow has been reshaped when passing through a switch then switches using these methods base their feedback on uncertain information. This may lead to a decrease in fairness and even to increased cell loss.

I.5.2.1 EPRCA

This scheme was considered as an enhancement to the Proportional Rate Control Algorithm where the source sends RM-cells at a rate proportional to its current rate. The RM-cells sent by the source contain a desired explicit rate (ER), the current cell rate usually set to the allowed cell rate (ACR) and the congestion indication bit CI set to zero. The switch computes a mean allowed cell rate for all connections (MACR) using a running exponential weighted average. MACR is computed by MACR = $(1-\alpha)$ MACR + α CCR, where α is generally chosen to be 1/16, weights the MACR more than the current CCR. The switch monitors its load by keeping track of the queue length. When the RM-cell returns from the destination the switch reduces the ER field if it is in a state of congestion. In this scheme the fair share was computed to be a fraction 7/8 of the MACR. If the value in the ER field is less than the fair share no adjustments are made. On the other hand if the value is higher and the switch is in a congested state the value is lowered to its fair share.

I.5.2.2 Congestion Avoidance Schemes

In this scheme the rate of change of queue length is used as a load indicator. The load factor is defined as z = Input rate/Target rate. The input rate is measured over a fixed averaging interval and the target rate is set slightly below the link bandwidth, e.g., 85-90%. There are two variations of this scheme that differ in the algorithm used to compute the fair share or explicit rate based on the load factor.

I.5.2.3 ERICA

ERICA (Explicit Rate Indication for Congestion Avoidance) tries to maintain the network at a load z close to one. In its simplest form, it calculates two quantities: fairshare, and this connection's share:

```
Fairshare = Target capacity / Number of active connections VCshare = CCR / z.
```

Here CCR is the current cell rate field in the RM-cell that contains ACR declared by the source (or as measured by the switch). This scheme achieves fairness concurrently with efficiency by using the following formula to compute the explicit rate (ER):

```
ER = Max (Fairshare, VCshare).
```

The above quantities are measured periodically using information from the forward RM-cells, and the feedback is given in the backward RM-cells. This ensures that the most current information is used to provide fastest feedback. The measurement interval is independent of the rate at which the sources send RM-cells. For each interval, no more than one new explicit rate value is advertised per-connection. This avoids conflicting feedback to sources due to stale information at the switches. The scheme has few parameters that can be easily tuned. There are a few other variations of this scheme.

I.5.2.4 Congestion Avoidance using Proportional Control (CAPC)

Again as in the previous scheme the target utilization is set to be slightly less than one, and the load factor is computed. The load factor is used to update the fair share, which is computed differently depending on whether z<1 or z>1. During underload, the fair share is increased by the formula Fair share = Fair share * Min(ERU, 1+(1-z)*Rup). Rup is a slope parameter between 0.025 and 0.1 and ERU determines the maximum increase allowed in the allotment of fair share. When z>1, the fair share is decreased according to Fair share = Fair share * Max(ERF, 1- (z-1)*Rdn) where Rdn is between 0.2 and 0.8 and ERF set to 0.5 determines the maximum decrease in the fair share.

I.5.2.5 ER based on bandwidth Demand Estimate Algorithm

The Mean Allowed Cell Rate (MACR) computed at the switch is based on a running exponential average of the ACR value read from each connection's forward RM-cells. MACR is given by MACR = MACR + (ACR - MACR) * AVF (e.g., AVF = 1/16). If the load factor (Input Rate/Target Rate) is < 1, the leftover bandwidth is reallocated according to MACR = MACR + MAIR, where MAIR is the MACR Additive Increase Rate (e.g., MAIR = .5 Mb/s). A positive queue derivative indicates an increasing bandwidth demand that causes the switch to enter a congestion state, The ER value computed is then ER = MACR * MRF (e.g., MRF = .95), if the switch has detected congestion. Otherwise, ER = MACR.

I.5.3 Reactive Switch Behavior

A reactive switch can be used to partially segment an ABR control loop. It assumes an ER mode of switch operation. The objective of using reactive switches is to take advantage of short control loops to reduce reaction time to congestion and limit buffer requirements, without implementing full VSVD behavior. It requires dynamic shaping of traffic on a per-connection basis.

The rules of RS operation are:

- An RS assumes the behaviors of an ABR switch as specified in Section 5.10.6
- An RS monitors backward RM-cells in order to extract the content of the ER field
- An RS may never transmit cells of a particular connection at a rate greater than that specified in the ER field of the last received backward RM-cell for that connection.

I.5.4 Sample Explicit Rate VS/VD Switch Algorithm Using ERICA+

One method to implement a VS/VD is to have a separate queue (per-connection queue) for each connection. A server at the head of each of these queues monitors the input rate of the queue, provides feedback to the upstream queue, and controls the output rate of the queue based on the feedback from the corresponding downstream server. When providing feedback, each server only allocates up to the rate at which it is allowed to output (ACR). However, if queues are large, the server may allocate only a part of its ACR to the previous hop so that its queues can drain quickly. The main features and options of the algorithm are similar to the ERICA+ algorithm. ERICA+ is an extension of the ERICA algorithm, and uses queue length to dynamically set the target ABR capacity.

The basic rate allocation algorithm consists of the following steps at the end of every averaging interval. The port overload is calculated as the ratio of the total measured service rate of the per-connection queues and the target ABR capacity. The fair share term for connections is calculated as the ratio of the target ABR capacity to the number of active ABR connections. VCshare is calculated for each connection as the ratio of its measured service rate to the overload. The ER for each connection is calculated as ER = Min(Max(Fair Share, VCshare), ER from downstream node). The ACR at which the connection's queue drains is determined from this ER as well as the source-end-system rules for the VS. The feedback to the previous hop for the connection is calculated as a fraction (based on the connection's queue length) of the calculated ACR.

I.6 Turning RM-Cells Around

I.6.1 Introduction

The purpose of this section is to explain the behavior of the various allowed possibilities of turning around received forward RM-cells as specified in destination behavior #3.

Destination Behavior #3 states:

If a forward RM-cell is received by the destination while another turned-around RM-cell (on the same connection) is scheduled for in-rate transmission:

- a) It is recommended that the contents of the old cell are overwritten by the contents of the new cell.
- b) It is recommended that the old cell (after possibly having been overwritten) shall be sent out-of-rate; alternatively the old cell may be discarded or remain scheduled for in-rate transmission.
- c) It is required that the new cell be scheduled for in-rate transmission

Given that behavior #3b specifies 3 options of what to do with the old waiting cell, and behavior #3a specifies 2 options of what the contents of the old waiting cell can be, there are a total of 6 possibilities represented by destination behavior #3.

However, if the old cell is discarded (the second option of #3b), it makes no difference whether its contents were overwritten or not. As a result, there are really only 5 possibilities for the relationship between newly received forward RM-cells and previously received forward RM-cells that are awaiting in-rate transmission.

These 5 possibilities are:

- 1. The newly arrived cell's contents are sent as an out-of-rate backward RM-cell in addition to being scheduled for in-rate transmission. (This follows recommendations of behaviors #3a and #3b.)
- 2. The old cell's contents are sent as an out-of-rate backward RM-cell and the newly arrived cell is scheduled for in-rate transmission. (This follows the recommendation of #3b but does not follow the recommendation of behavior #3a.)
- 3. The newly arrived cell is scheduled for in-rate transmission and the old cell is dropped. (This follows the discard alternative of #3b. It makes no difference whether the recommendation of #3a was followed or not.)

- 4. Two copies of the newly arrived cell are scheduled for in-rate transmission. (This follows the recommendation of #3a and follows the "remain scheduled" alternative of behavior #3b.)
- 5. Both the old cell and the newly arrived cell are scheduled for in-rate transmission. (This does not follow the recommendation of behavior #3a and follows the "remain scheduled" alternative of behavior #3b.)

These 5 possibilities will be referred to as options 1 - 5 throughout the rest of this section.

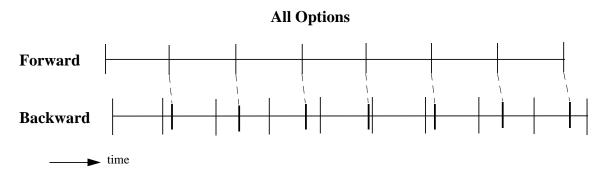

The first part of this section discusses options 1, 2, and 3. Options 4 and 5 are "queuing" options and will be discussed later in the section.

I.6.2 Behavior of the Non-Queuing Options

This section discusses and compares the behavior of options 1, 2, and 3. The behaviors are explored over the range of forward bandwidth (ACRfwd) and backward bandwidth (ACRbck). The specific cases discussed are ACRbck > ACRfwd, ACRfwd > ACRbck, ACRfwd >> ACRbck, and ACRbck= 0.

I.6.2.1 ACRbck > ACRfwd Introduction

A diagram showing the case where the backward ACR is greater than the forward ACR is shown in the following figure:

Vertical lines represent RM-cells. Longest lines are forward RM-cells. Middle length lines are in rate backward RM-cells. Shortest lines are out of rate backward RM-cells. All vertical lines on the forward links represent forward RM-cells.

In this illustration, RM-cell flow in both the forward and backward direction is illustrated. Time flows from left to right. Vertical lines represent RM-cells (data cells are not represented). The length of the vertical lines determines the type of RM-cell. Longest lines are the forward RM-cells, middle length lines are the in-rate backward RM-cells, and the shortest vertical lines are the out-of-rate backward RM-cells. Note that only forward RM-cells are shown in the forward cell flow but both forward and backward RM-cells are shown in the backward cell flow. The above illustration contains only forward RM-cells and in-rate backward RM-cells. Out-of-rate backward RM-cells are represented in later illustrations.

In addition, dotted and dashed lines are used to show which received forward RM-cell's contents became which backward RM-cell. To help differentiate (in the absence of color) between in-rate and out-of-rate backward RM-cells, dashed lines are used to show a forward RM-cell's contents that became an in-rate backward RM-cell and dotted lines are used to show a forward RM-cell's contents that became an out-of-rate backward RM-cell.

In this specific case where the ACR of the backward direction is greater than the ACR of the forward direction, it is obvious that all backward RM-cells will be sent in-rate with all three options. Source Behavior #3 will allow for the backward RM-cell to be sent at the next available cell time in the backward direction with all three options, and, therefore, the behavior of all three options will be the same.

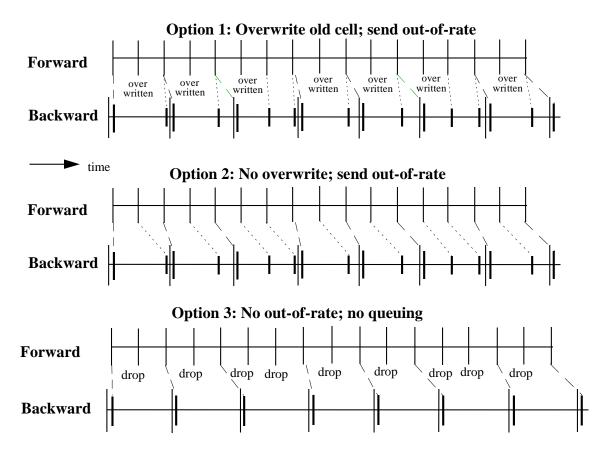

The case where ACRbck > ACRfwd is the ideal case for in-rate backward RM-cells.

I.6.2.2 ACRfwd > ACRbck

As the backward ACR becomes lower than the forward ACR, differences begin to emerge in the operation of the different optional behaviors. The following diagram shows the behavior of each of the option combinations when the backward ACR is less than the forward ACR (but not tremendously less).

Before contrasting the differences in the 3 options, it is important to discuss their similarities. One of the most important properties of destination Behavior #3 is the assurance that in-rate backward RM-cells will be transmitted as often as possible given the frequency of received forward RM-cells and source behavior #3. When the ACR in the forward direction is greater than the ACR in the backward direction, every possible chance to send in-rate backward RM-cells should be taken. The requirement of destination behavior #3c insures that this will be true. All 3 of the options above reflect the fact that an in-rate backward RM-cell is sent at every opportunity (according to source behavior #3).

Now, contrast the operation of options 1 and 2 above. The difference between the two options is that option 1 overwrites the old cell before transmitting it out-of-rate (therefore transmitting the newly arrived cell's contents out-of-rate) and option 2 does not. Both options schedule the newly arrived cell for in-rate backward RM-cell transmission.

Vertical lines represent RM-cells. Longest lines are forward RM-cells. Middle length lines represent in-rate backward RM-cells. Shortest lines are out-of-rate backward RM-cells. All vertical lines on the forward links represent forward RM-cells.

The frequency and spacing of both in-rate and out-of-rate backward RM-cells are the same with both options. The difference is that option 1 always transmits the latest information in out-of-rate backward RM-cells and option 2 does not.

The ramifications of old vs. new information in backward RM-cells will now be further explored. It is advantageous to transmit the latest RM-cell data in the presence of explicit rate switches that modify the explicit rate field in the forward direction or that monitor the CCR field of the RM-cell (in either the

forward or the backward direction). Also, out-of-rate backward RM-cells may not be able to be transmitted immediately because of higher priority traffic (CBR or VBR). If the out-of-rate backward RM-cell is different than the awaiting in-rate backward RM-cell, there will need to be storage capability for 2 backward RM-cells per-connection. These are some of the reasons behind the recommendation of behavior #3a which leads to option 1.

However, option 1 has a characteristic that needs to be examined. Option 1 has the possibility of duplicating the contents between an out-of-rate backward RM-cell and the next in-rate backward RM-cell. In fact, whenever there are out-of-rate backward RM-cells with option 1, the next in-rate backward RM-cell will be a duplicate (except for the CI bit) of the last out-of-rate backward RM-cell. This duplication is illustrated in the above figure.

The reality is that this duplication has no adverse effect on ABR operation. In the case of explicit rate switches, it simply means that the explicit rate and the current cell rates of backward RM-cells will always be the latest that are available. In the case of binary mode switches, if the CI bit is set as the backward RM-cell is being transmitted (as preferred from destination behavior #2b), then the backward RM-cell always carries the latest EFCI state.

Since the duplication has no effects on either explicit mode or binary mode networks, since there are definite advantages to carrying the latest information in backward RM-cells, and since there are implementation advantages in the end stations if only a single RM-cell's contents needs to be saved, option 1 is recommended over option 2.

Option 3 does not support out-of-rate backward RM-cells at all. It can be seen in the figure that, as the backward ACR falls below the forward ACR, received forward RM-cells begin to be dropped and the number of backward RM-cells begins to drop well below the number of received forward RM-cells. The responsiveness of the forward ACR control loop will be lessened by the decrease in frequency of backward RM-cells.

I.6.2.3 ACRfwd >> ACRbck

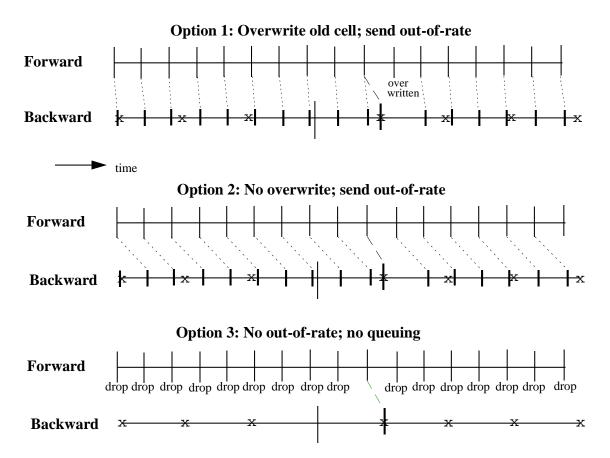

Now, the behavior when the forward ACR is much larger than the backward ACR is explored. The following diagram illustrates the different option combinations under this condition.

Vertical lines represent RM-cells. Longest lines are forward RM-cells. Middle length lines represent in-rate backward RM-cells. Shortest lines are out-of-rate backward RM-cells. All vertical lines on the forward links represent forward RM-cells.

In this case, the rate of forward RM-cells is greater than the cell rate in the backward direction. Notice now that individual in-rate cell opportunities are shown in the backward channel representations. In-rate cell opportunities are represented as x's.

Once again, options 1 and 2 produce the same frequency and spacing of both in-rate and out-of-rate backward RM-cells. Again, with both options, the total number of backward RM-cells (both in-rate and out-of-rate) equals the number of received forward RM-cells.

Option 3 drops most of the received forward RM-cells. With the very limited number of in-rate backward RM-cells in this case, the responsiveness of the forward direction ACR control loop may be very limited.

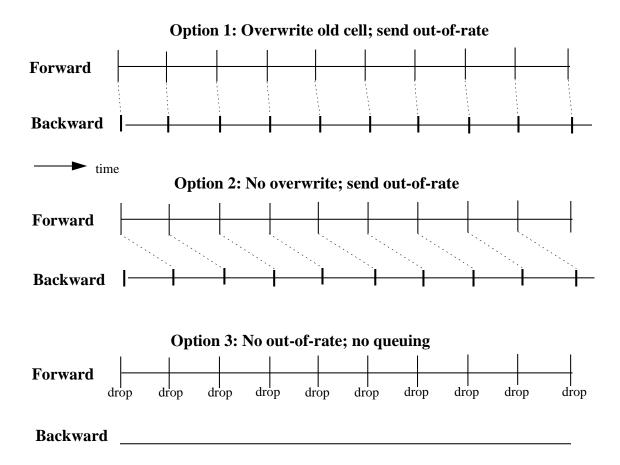

I.6.3 Backward ACR = 0

The analysis continues with the backward ACR dropping all the way to zero. The following diagram shows the behavior of all option combinations with this case.

In this case, since there are no in-rate slots in the backward direction, both option 1 and option 2 send nothing but out-of-rate backward RM-cells. The only difference between these two options is in the latency of the out-of-rate backward RM-cell's contents. Option 1 transmits the newly arrived forward RM-cell's contents as the out-of-rate backward RM-cell and option 2 transmits the old forward RM-cell's contents as the out-of-rate backward RM-cell.

Notice that there are no backward RM-cells at all in option 3. There are no in-rate cell slots and option 3 does not implement out-of-rate backward RM-cells. Any end station implementing option 3 for backward RM-cell handling cannot operate in a situation where the backward ACR is 0. There must be sufficient MCR in the backward direction to allow for enough in-rate backward RM-cells to effectively implement the forward ACR control loop.

I.6.4 Behavior of the Queuing Options

Options 4 and 5 from Section I.6.1 represent queuing options for in-rate backward RM-cells. A queue for in-rate backward RM-cells is in order if there is a desire to handle a situation where clumping of forward RM-cells occurs. A queue allows for the received clumped RM-cells to be sent in successive in-rate backward RM-cell slots. Without a queue, much of the clump of received RM-cells will be transmitted as out-of-rate backward RM-cells. An illustration of a case where the forward and backward ACRs are equal and a clump of forward RM-cells is received is shown in the following figure.

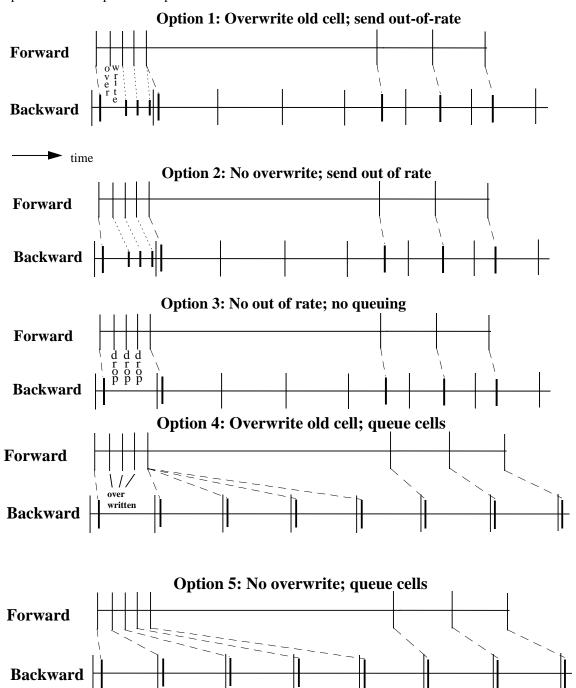

Notice that the difference between options 4 and option 5 is that option 4 always uses the latest received forward RM-cell's contents while option 5 keeps the older RM-cells' contents in the queue. The queue of option 4 could be implemented with a counter along with a single RM-cell storage area. Option 5 requires a storage area for each of the queued RM-cells.

It is also important to discuss what will happen in a queued backward RM-cell implementation when the queue fills. Recall that a queue may be desired to handle the situation where clumping of forward RM-cells has occurred in the network. However, a queue does nothing to handle the situation where the forward ACR is larger than the backward ACR. In this case, the queue will fill. When the queue fills, the implementation can use either option 1, option 2, or option 3 to handle subsequently received forward RM-cells.

Using option 3 to handle queue overflow is simple to comprehend. When a forward RM-cell is received and the queue is full, the head of the queue will be discarded and the newly received forward RM-cell will be added to the tail of the queue. This works whether the queue was implemented with option 4 or option 5.

Using option 2 to handle queue overflow is also simple to comprehend. When a forward RM-cell is received and the queue is full, the head of the queue will be sent as an out-of-rate backward RM-cell and the newly

received forward RM-cell will be added to the tail of the queue. Again, this works whether the queue was implemented with option 4 or option 5.

A little care must be taken in using option 1 to handle queue overflow. Recall that option 1 sends the contents of the newly arrived forward RM-cell as an out-of-rate backward RM-cell in addition to queuing it for in-rate backward RM-cell transmission. If the backward RM-cell queue is implemented using option 5 (where old cells are not overwritten with the contents of the newly arrived cell), then all cells in the queue would need to be flushed if the newest forward RM-cell was sent as an in-rate backward RM-cell (see destination behavior #4). If the backward RM-cell queue is implemented using option 4, then there is no problem.

I.6.5 Summary

The advantage of using one of the queuing options (option 4 or option 5) is that network clumping of forward RM-cells can be handled more elegantly. The disadvantage to using one of the queuing options (besides the increase in complexity) is that there will be a longer time before an out-of-rate backward RM-cell is transmitted when the backward ACR becomes smaller than the forward ACR. The queue must fill before an out-of-rate backward RM-cell will be sent. (If the destination does not wait for the queue to fill, there is the possibility of transmitting more backward RM-cells than received forward RM-cells.)

If a non-queued turn-around RM-cell implementation is desired, the recommendations of destination behavior #3 imply that option 1 of this section is the desired mode of operation in turning around received forward RM-cells. It has the properties of always transmitting the latest RM data, always using available in-rate backward RM-cell slots, making full use of allowed out-of-rate backward RM-cell possibilities, and allowing for only one set of backward RM-cell contents to be stored awaiting transmission by the destination.

Option 2 is the second more desirable of the non-queued options since it implements the recommendation of behavior #3b but not of behavior #3a. Option 3 is the least desirable of the 3 non-queued options.

Of the queued RM-cell implementations, option 4 is the most desired mode of operation. It implements the recommendation of behavior #3a which allows for only the latest RM-cell information to be transmitted. It can also be simpler to implement than option 5. If the queue implemented in option 4 overflows, the recommended procedure is to follow the recommendations of behavior #3a and #3b and send the contents of the newly arrived RM-cell as an out-of-rate backward RM-cell while keeping it scheduled for in-rate transmission.

I.7 End-System Congestion and Optional Use-it-or-lose-it Behavior

Situations will arise where an ABR end-system will not be able to send cells as fast as the ACR allows. This could be due to application or end-system architecture constraints, such as contention for access to a disk. Another possible cause is local scheduler congestion, which occurs when the sum of ACRs to be scheduled exceeds the link rate. Use-it-or-lose-it behavior reduces the ACR assigned to a connection if that connection is transmitting significantly below its ACR. The objective of use-it-or-lose-it behavior is to ensure that ACR is maintained reasonably close to the real cell transmission rate.

Although the source may choose to support use-it-or-lose-it behavior to help protect the switches, it is the responsibility of the switches to support QoS objectives for ABR connections that conform to the mandatory ABR behaviors.

Use-it-or-lose-it behavior may be beneficial in the following circumstance:

Temporarily rate limited sources may jump to their acquired ACR at any time, causing an unexpected step increase in the arrival rate at switches on its path. These kind of jumps occur as contention for application or scheduler resources fluctuates. Use-it-or-lose-it behavior can reduce these transient fluctuations in traffic load. For networks with binary switches it can reduce the control lag experienced after transitions from underload to overload. Keeping ACR close to the real rate reduces the number of CI=1 RM-cells required to reduce ACR by an amount sufficient enough to control the actual cell transmission rate.

Note however, that by reducing ACR, use-it-or-lose-it behavior can reduce the performance of request response applications. In addition, sources implementing use-it-or-lose-it behavior may be at a fairness disadvantage with respect to sources that do not implement use-it-or-lose-it behavior.

The means by which use-it-or-lose-it behavior is achieved is implementation specific. Some example methods include:

End-system method 1: forward RM-cell triggered
 When an in-rate forward RM-cell is sent, if the ACR exceeds the recent transmission rate plus a fixed bound, the ACR is reduced by a multiplicative factor and the next increase inhibited. Specifically the recent rate R, could be estimated by Nrm divided by the time since the last in-rate forward RM-cell

was sent. If ACR exceeds R+ICR, the ACR could be set to the higher of ACR*15/16 and R+ICR, and the next increase inhibited.

- End-system method 2: backward RM triggered
 When a backward RM is received, the ACR increases are limited such that the resulting ACR it is not significantly greater than the recent transmission rate R. Specifically the received ER could be reduced to R+ICR.
- End-system method 3: Internal congestion algorithm
 The end-system might run an implementation specific switch algorithm internal to the end-system that reacts to internal scheduler congestion. To work effectively the scheduler must be able to schedule cells faster than the outgoing link rate. This kind of method does not respond to application level congestion, but does respond to scheduler congestion.
- Switch based:
 The use-it-or-lose-it can also be implemented in a switch that monitors each connections cell transmission rate and sends explicit rate messages to hold ACR within some implementation specific bound.

I.8 Sample Branch Point Algorithms for Multipoint ABR Flow Control

A branch point replicates cells from the root to each branch in the responding state and consolidates their feedback. One method of consolidating information from BRM cells is to assign the ER field in returning RM cells to the minimum of the ER values indicated by the branches, the CI to the OR of the indicated CI values, and the NI to the OR of the NI values. In the sample algorithms given next, we show the assignment of the ER value; CI and NI values can be assigned in a similar manner.

In a sample point-to-multipoint ABR algorithm, the minimum explicit rate indicated by the BRM cells received from the branches each iteration is maintained, say as MER. Whenever an FRM cell is received at a branch point, it is multicast to all branches, and the algorithm sets a flag indicating the receipt of the FRM cell. When a BRM cell is received from a branch, it is passed back towards the source (using ER = min (MER, ER)), only if the flag was set. The flag is then reset and MER set to PCR. If the flag was not set, MER is updated to min (MER, ER in BRM cell) and the BRM cell is discarded.

Consolidation noise can occur when feedback from some leaves is not always received in a timely fashion at the time when the RM cells need to be returned by the branch point. To reduce consolidation noise, the BRM cell can only be passed back towards the source when BRM cells from all branches have been received after the last feedback. This can be done by maintaining a separate flag for each branch to indicate if a BRM cell has been received from the branch after the last BRM cell was sent. It is important to handle the possible non-responsiveness of a branch in this algorithm. The slow transient response in this algorithm, caused by waiting for feedback from possibly distant leaves, can be avoided when a severe overload situation has been detected (fast overload indication). In this case, the algorithm can avoid waiting for feedback from all the branches, and overload information can be immediately indicated to the source. In the cases when the branch point is itself a switch and queuing point, the branch point can invoke the switch scheme to compute the new ER value whenever a BRM is received, and not only when a BRM is being sent. Hence, overload at the branch point itself can be detected and indicated according to the fast overload indication idea.

The fast overload indication may increase the BRM cell overhead, since the ratio of source-generated FRM cells to BRM cells received by the source can exceed one. One method to alleviate this problem is to increment a counter (maintained for each multipoint connection) whenever a BRM cell is sent before feedback from all branches has been received. When feedback from all branches indicates underload, and the value of that counter is more than zero, this particular feedback can be ignored and the counter decremented.

Informative Appendix II: Conformance Examples in a Traffic Contract

II.1 Introduction

In the traffic contract, the Cell Delay Variation tolerance specified at the UNI is defined in relation to the PCR by the GCRA and the BT specified at the UNI is defined in relation to the SCR also by the GCRA. Additionally, a conformance definition that defines the combination of GCRAs in relation to the different cell streams and cell rates of a connection at the UNI is also specified in the traffic contract. Depending upon the services provided, different conformance definitions could be specified. In this appendix, a few examples are given for information purposes.

For each example described herein, the service needs are summarized and then followed with a conformance definition that *could* be used to accommodate the service needs. Specifically, the examples illustrate how one can emulate the traffic definitions of various services by appropriately mapping them into parameters of various GCRAs. The specific conformance definition used is for illustrative purposes. Figures are also provided in the form of block diagrams to depict how various GCRAs interact with each other. Two functional blocks are used to represent the high level flowchart of a GCRA(I, L) algorithm and are labeled by C(I) and U(I):

1. Conformance Checking Functional Block:

C(I)

2. Update Functional Block:

U(I)

The conformance checking functional block represents functions performed in order to determine whether a cell is conforming or not. The update functional block represents the update function performed if a cell is identified as conforming. Note that the only purpose of the block diagrams are to test conformance to the traffic descriptors as defined by the conformance definition. The conformance definitions indicated in these examples should not be interpreted as the UPC algorithms. Hence, non-conformance does not imply a discard or tagging decision.

II.2 Example 1: Switched Multi-megabit Data Service (SMDS)

SMDS allows customers to send bursts at the full access link rate (e.g., DS3 PLCP). To control the sustainable information rate, an I_{inc} , a N_{inc} , and a C_{max} are specified. I_{inc} is the interval (in 53-octet slot times) between increments to the credit. N_{inc} is the number of credits (in user information octets) increase per increment. I_{inc} and N_{inc} together determine a maximum sustainable information rate. C_{max} is the maximum credits that can be accrued. C_{max} is 9188 octets for all access classes. An arriving message will be discarded, if the current accrued credits are less than the estimated user information length.

For an ATM connection supporting the above SMDS application, the following conformance definition (VBR.1, see Section 4.5.2.1) in relation to a source traffic descriptor that specifies the PCR for the CLP=0 cell stream and SCR for the CLP=0+1 cell stream *could* be specified in the traffic contract *if a proper minimum user information length that the SMDS user could submit is imposed:*

For an ATM connection supporting the above SMDS application, the following conformance definition (VBR.1) *could* be specified in the traffic contract:

- 1. One GCRA(T₀₊₁, CDVT) defining the CDVT in relation to the PCR of the CLP=0+1 cell stream.
- 2. One GCRA(T_{SO+1} , BT_{0+1} + CDVT) defining the sum of the BT and CDVT in relation to the SCR of the CLP=0 cell stream.

A cell that is conforming to both GCRAs (1) and (2) above is said to be conforming to the connection traffic descriptor. The tagging option is not applicable to this conformance definition.

PCR could be chosen to emulate the original SMDS access line rate. The values of PCR and SCR should be chosen to include the extra margin required to accommodate the overhead introduced in transferring the user information via an ATM network in order to deliver an equivalent maximum sustainable information rate to the user. This overhead is closely related to the SMDS message length distribution. The BT_{0+1} should be set to allow the maximum burst accepted in SMDS to be passed at the PCR.

Figure II-1 depicts this conformance definition in terms of the GCRA functional block diagrams. Although traffic conformance at the UNI is defined by this definition, the network may use any UPC mechanism as long as the QoS objectives are met for compliant connections.

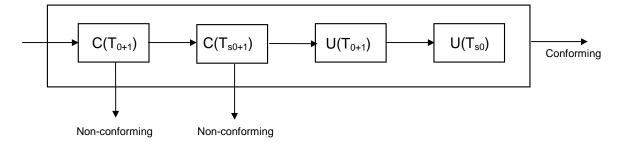

Figure II-1: Example 1

II.3 Example 2: Frame Relay Service (FRS)

FRS allows customers to send bursts at the full access link rate (e.g., DS1). To control the sustainable information rate, a B_C , a B_e , and a CIR are specified. The measurement interval T is derived and is equal to B_C/CIR . The excessive information rate (EIR) is also derived and is equal to $B_{C'}/T$.

- When a frame with discard eligibility indication not set arrives,
 - a. if the current accrued credits for *CIR* is greater than or equal to the frame length, send the frame:
 - b. if the current accrued credits for *CIR* is less than the frame length, but the current accrued credits for *EIR* is greater than or equal to the frame length, the frame is sent with discard eligibility indication set;
 - c. if the current accrued credits for *CIR* is less than the frame length and the current accrued credits for *EIR* is also less than the frame length, the frame is discarded.
- When a frame with discard eligibility indication set arrives and,
 - a. if the current accrued credits for *EIR* is greater than or equal to the frame length, send the frame,
 - b. if the current accrued credits for EIR is less than the frame length, discard the frame.

The maximum number of credits that can be accrued for CIR is B_C . The maximum number of credits that can be accrued for EIR is B_C .

The intent of this section is to provide an example of the interworking of ATM and Frame Relay where the ATM connection is described by two GCRAs. The restriction to two GCRAs leads to a limitation in matching the ATM parameter to the *EIR* or the Frame Relay access line rate.

For an ATM connection supporting the above FRS application, the following conformance definition (VBR.3, see Section 4.5.2.3) in relation to a source traffic descriptor that specifies PCR for the CLP=0+1 cell stream, SCR for the CLP=0 cell stream *could* be specified in the traffic contract *if a proper minimum frame length that the FRS user could submit is imposed.*

- 1. One GCRA(T₀₊₁,CDVT) defining the CDVT in relation to the PCR of the aggregate CLP=0+1 cell stream.
- 2. One GCRA(T_{S0}, BT₀+CDVT) defining sum of the BT and CDVT in relation to the SCR of the CLP=0 cell stream.

A CLP=0 cell that is conforming to both GCRAs (1) and (2) above is said to be conforming to the connection traffic descriptor. A CLP=1 cell that is conforming to GCRA (1) above is said to be conforming to the connection traffic descriptor. A CLP=0 cell that is not conforming to GCRA (2) above but is conforming to GCRA (1) above is considered to have the CLP bit changed to 1 and said to be conforming to the connection traffic descriptor.

The values of PCR and SCRs should be chosen to include the extra margin required to accommodate the overhead introduced in transferring the FRS frames via an ATM network. When the PCR is chosen to emulate the FRS access line rate, the *EIR* that is allowed is the difference between the access line rate and the *CIR*. Therefore, the *EIR* that is allowed possibly exceeds the *EIR* negotiated for the FRS. However, using traffic shaping, the PCR may be chosen to be the higher of either the required value to achieve the Transfer Delay objectives, or the required value to achieve the sum of *CIR* and *EIR* to the user. The BT_0 should be set to allow the maximum committed burst accepted in FRS to be passed at the PCR.

Figure II-2 depicts this conformance definition in terms of the GCRA functional block diagrams. Although traffic conformance at the UNI is defined by this definition, the network may use any UPC mechanism as long as the QoS objectives are met for compliant connections.

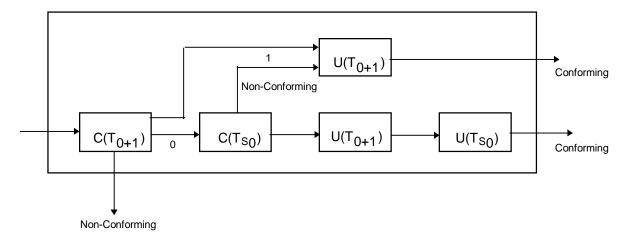

Figure II-2: Example 2

The conformance definition that defines the traffic descriptor can be such that cells that are not conforming with the CLP=0 SCR parameter set may or may not be submitted as CLP=1 cells through marking at the source. In this case the single CLP bit in the ATM header carries two meanings; one for user marked CLP=1 cells and the other for the tagged cells. The network (i.e., the switches) cannot distinguish between the two meanings. Therefore, the same QoS objectives are supported for both the user marked CLP=1 cells and the network tagged CLP=1 cells.

II.4 Example 3: Constant Bit Rate Services

For an ATM connection supporting a Constant Bit Rate service, the following definition (see Section 4.5.1) in relation to a source traffic descriptor that specifies PCR for the CLP=0+1 cell stream *could* be specified in the traffic contract:

1. One GCRA(T_{0+1} ,CDVT) defining the CDVT in relation to the PCR of the CLP=0+1 cell stream.

A cell that is conforming to this GCRA is said to be conforming to the connection traffic descriptor. PCR is chosen to emulate the constant bit rate of the service.

Figure II-3 depicts this conformance definition in terms of the GCRA functional block diagrams. Although traffic conformance at the UNI is defined by this definition, the network may use any UPC mechanism as long as the QoS objectives are met for compliant connections.

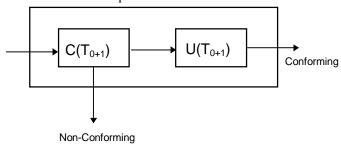

Figure II-3: Example 3

II.5 Example 4: LAN Interconnection

In applications such as LAN interconnection, multiple workstations on a LAN can send data over a public or private ATM WAN to other workstations in other LANs. These LANs can be interconnected through VPCs across the ATM backbone. In this example it is assumed that a VBR.3 VPC is used (see Section 4.5.2.3). In such applications, the user's frames typically have the same level of importance and therefore are submitted to the ATM network as CLP=0 cells (after being processed at the AAL). Since traffic from multiple workstations are multiplexed on a given VP, there may not be a traffic shaper on the user side of the UNI (this may particularly be the case at the private-UNI). In such applications, it is desirable for the network to tolerate some amount of non-conformance of the CLP=0 stream by tagging these non-conforming cells as CLP=1 cells. This allows the users not to be very pessimistic in their traffic description and therefore may avoid excessive "over-allocation" for bursty data applications.

Informative Appendix III: Examples of ABR conformance and compliance definitions

III.1 Dynamic GCRA: An Example of a Conformance Definition

The Dynamic GCRA (DGCRA), an extension of the GCRA algorithm, may be used to specify conformance to Explicit-Rate (ER) feedback at the public or private UNI, the Private NNI, or the BICI for the cell flow of an ABR connection. The DGCRA objectively defines ER-conformance on a cell-by-cell basis and thus establishes the number of ER-conforming cells on the connection over any specified interval. If ER-conformance is used by the network as the definition of conformance more generally, then the number of ER-conforming cells on a compliant connection is a lower bound on the number of cells for which QoS objectives should apply. In this way, the definition of ER-conformance can serve as a constraint on the design of UPC algorithms. It is not necessarily intended as a UPC algorithm itself.

The DGCRA differs from the GCRA defined in Section 4.4.2 primarily in that the increment I changes with time, as determined by ABR feedback information conveyed on the corresponding backward connection. The DGCRA checks the conformance of all CLP=0 cells on the ABR connection. The increment I may change on the arrival of any CLP=0 cell on the connection, and the increment calculated on the arrival of the k^{th} CLP=0 cell on the connection is denoted by I(k). At the arrival time $t_a(k)$ of this k^{th} cell, the DGCRA algorithm first calculates I(k) and then checks the cell's conformance and updates its own Last Virtual Scheduling Time (LVST) as follows:

Initialize: $LVST=t_a(1)$, Iold=I(1).

At each arrival time $t_a(k)$ of a CLP=0 cell for $k \ge 2$,

- if $t_a(k) \ge LVST + \min(I(k), Iold) \tau_1$, /*cell is conforming*/
 then set $LVST = \max(t_a(k), LVST + \min(I(k), Iold))$ and Iold = I(k);
- otherwise /* cell is nonconforming*/
 do not update algorithm state.

The tolerance τ_1 , which accommodates jitter or bursts, is a constant that does not depend on k. In the special case where I(k)=I (a constant) for all k, the above algorithm is equivalent to GCRA(I, τ_1). The DGCRA accounts for the option of the source to reschedule the next cell transmitted on a connection when new feedback is received.

The selection of I(k) depends on two additional delay parameters τ_2 and τ_3 for the connection. The interval I(k) must satisfy the constraints that I(0) = I/ICR and that I/PCR <= I(k) <= I/MCR for $k \ge 1$, where MCR is the Minimum Cell Rate and PCR is the Peak Cell Rate for the connection. The DGCRA algorithm, with the parameters PCR, MCR, ICR, τ_1 , τ_2 , and τ_3 , and is denoted by $DGCRA(MCR^{-1}, PCR^{-1}, ICR^{-1}, \tau_2, \tau_3)$.

The sequence $\{I(k), k \ge 1\}$ of increments, which are successively used at arrival times $\{t_a(k), k \ge 1\}$ of CLP=0 cells at the interface, depends on the sequence $\{ER(j), j \ge 1\}$ of explicit rates sent across the interface at departure times $\{t_b(j), j \ge 1\}$ of CLP=0 backward RM-cells on the backward connection. The DGCRA defers mapping increases in the sequence $\{ER(j)\}$ of explicit rates into the increments $\{I(k)\}$ until after a lag τ_a , and defers mapping decreases in $\{ER(j)\}$ into $\{I(k)\}$ until after a lag τ_a . This accommodates the behavior of a connection that requires at least a time τ_a and at most a time $\tau_a > \tau_a$ to affect the instructed changes in the rate at which cells arrive at the interface. In addition to checking the use by the source of explicit-rate feedback, the DGCRA also checks for consistency with the specified ABR source behavior under RM-return-failure conditions.

Two algorithms A and B for determining the increment I(k) are presented below. Algorithm A results in a tighter conformance test, but does so at the expense of needing to keep track (possibly via a linked list) of a potentially large number of scheduled changes to these increments over a moving interval of length τ_2 minus τ_3 . Algorithm B is a simpler test where at most two scheduled changes need to be stored.

III.2 Algorithm A to Determine I(k)

Algorithm A uses the following algorithm to define the potential allowed cell rate $\{PACR(k), k \geq 1\}$ from which the increment $\{I(k), k \ge 1\}$ is derived by taking the inverse:

Initialize:
$$t_a(0) = 0$$
, $Ccount = 0$, $t_{ICR} = 0$, $t_f = INFINITY$

At each arrival time $t_a(k)$ of a CLP=0 cell for $k \ge 1$,

- if cell k is a forward RM-cell
 - if the previous arrival time t_f of a CLP=0 forward RM-cell satisfies

$$t_a(k) - t_f > ADTF + \tau_I$$

- set $t_{ICR} = t_a(k)$
- set $t_f = t_a(k)$

if the set of indices j of CLP=0 backward RM-cells such that $0 < t_b(j) \le t_a(k) - \tau_2$ is non-empty with largest element j_{max} , then

- if
$$t_b(j_{max}) < t_{lCR} - \tau_2$$

-set $PACR(k) = min (ER (j_{max}), ICR)$
otherwise
-set $PACR(k) = ER (j_{max}),$
- if $t_b(j_{max}) > t_a(k-1) - \tau_3$
 $Ccount = 0$
otherwise

if the set of indices j of CLP=0 backward RM-cells such that

- set PACR(k) = ICR.

```
t_a(k) - \tau_2 < t_b(j) \le t_a(k) - \tau_3 is non-empty, then
    - set PACR(k) = max (PACR(k), ER_{max}), where ER_{max} is the largest explicit rate ER(j) for j in
    - set Ccount = 0.
otherwise, if cell k is a CLP=0 forward RM-cell, then
```

- set Ccount = Ccount + 1.
- if Ccount > Crm, then
 - if cell k is a forward RM-cell,

$$PACR(k) = min(PACR(k-1)*(1-CDF), PACR(k)*(1-CDF))$$

otherwise

$$PACR(k) = PACR(k-1)$$

- PACR(k) = min(PCR, max(MCR, PACR(k))).
- I(k) = 1 / PACR(k)

Remark: The following text motivates the above definitions of the DGCRA. For this text we assume that no cells are lost and that the source behaves according to the ABR source reference behavior.

The rate change induced by a backward RM-cell departing from the interface (on the backward connection) at time t_b should be observed on the forward connection at some later time t_a such that

$$t_b + \tau_3 \le t_a \le t_b + \tau_2$$

If a cell arrives on the forward connection at time t, one can conclude the following:

a) The rate change due to a backward cells that passed at times t_b such that

$$t_a \ge t_b + \tau_2$$

will have taken place at the interface by time t_a (second bullet item above). If there are such RM-cells, one takes the most recent one with the index j_{max} and uses the Explicit Rate (ER) contained in this cell as the rate to be controlled.

- b) If a cell with index j_{max} has been identified, if the cell k is CLP=0 forward RM-cell, and if the previous forward CLP=0 RM-cell arrival time t_f satisfies $t_a(k)$ t_f > ADTF + τ_I one concludes that the reduction of ACR down to ICR (source behavior #5) has taken effect. If $t_b(j_{max}) < t_{ICR}$ τ_2 then the decrease to ICR must have occurred at the source after backward RM-cell j_{max} reached the source. In that case, PACR(k) is possibly further reduced by replacing ER (j_{max}) with min (ER (j_{max}), ICR) (first and second bullet items above).
- c) If no cell with index j_{max} can be identified, one takes ICR as the rate to be controlled.
- d) At the arrival of a forward cell at time t_a , *Ccount* is a lower bound on the number of forward RM-cells that have left the source since the last backward RM-cell that it received (as in Source Behavior #6). Backward RM-cells transmitted from the interface to the source at time t_b such that

$$t_a < t_b + \tau_3$$

should not have been received by the source before it had transmitted the cell arriving at the interface at time t_a . Thus, if the forward cell k-l arrived at time $t_a(k-1)$ such that

$$t_a(k-1) < t_b(j_{max}) + \tau_3$$

then the forward cell k-l must have left the source before the backward RM-cell departing the interface at time $t_b(j_{max})$ arrived at the source. If forward cell k then arrives at the interface at time $t_b(k)$ such that

$$t_a(k) \ge t_b(j_{max}) + \tau_2$$

it is considered to be the first cell leaving the source after the arrival there of the RM-cell j_{max} , so that *Ccount* is set equal to zero in this case (second bullet from above).

e) Backward RM-cells that passed at times t_b such that

$$t_b + \tau_3 \le t_a < t_b + \tau_2$$
.

may also have an impact on the rate at time t_a . To be on the safe side, one takes the maximum of these rates. Then one takes the maximum of this rate and the rate derived from part a)-c) above as the rate to be controlled (second bullet item above).

e) If Ccount > Crm and cell k is a forward CLP=0 RM-cell, PACR(k) has to reduced by CDF*PACR(k) (source behavior #6). At the same time, PACR(k) should be at most equal to the PACR at the last forward RM-cell times (1-CDF). But PACR at the last forward RM-cell is just PACR(k-1) since one sets PACR(k) to PACR(k-1) if the cell is not an RM-cell.

III.3 Algorithm B to Determine I(k)

Algorithm B, which follows, is a method to determine the increment I(k) for the DGCRA. The resulting conformance test is an approximation to the conformance test in Appendix III.2 in the following sense: At a forward CLP=0 cell arrival, the Potential Allowed Cell Rate (PACR) derived in the Algorithm B is greater than or equal to the PACR resulting from the conformance test in Appendix III.2. The proposed conformance algorithm meets the design constraints for an ABR conformance test stated in Section 4.5.4.

Like Algorithm A, Algorithm B derives the PACR from the explicit rates ER(j) received in the backward RM-cells. A received backward RM-cell results in a delayed increase or a delayed decrease of PACR. Rate increases are scheduled with a delay of τ_3 or earlier. Rate decreases are scheduled with a delay of τ_3 or later.

For the sake of simplicity, at most two rate change events are scheduled: The first event is scheduled at time t_first with delayed explicit cell rate DER_first. The second (and last) event is scheduled at time t_last with DER_last. DER_last when scheduled is always a decrease in rate. Whether an explicit rate ER(j) results in a rate increase or rate decrease is determined by comparing ER(j) with DER_first and with PACR. If ER(j) is

greater or equal to DER_first and PACR then a rate increase is scheduled. If ER(j) is smaller than DER first then a rate decrease is scheduled.

If a rate increase has been scheduled for time t_first and this rate has not yet taken effect, then a further rate increase uses the same scheduled increase time t_first with a rate equal to the maximum of the old DER_first and ER(j). This further rate increase takes then effect with a delay less than τ_3 while the first increase scheduled for time t_first takes effect with delay τ_3 . If the first rate change event is a rate decrease and this rate has not taken effect then a rate increase is scheduled for time t_first but not later than t_now + τ_3 . If a decreased delayed cell rate has been scheduled, then a another further rate decrease is scheduled for time t_last = tb(j) + τ_2 . Further rate decreases overwrite t_last until the first rate has taken effect.

The first part of the algorithm schedules rate increases or rate decreases after arrival of a backward RM-cell. The last part is used at the arrival of a CLP=0 cell in the forward direction to determine whether this cell is conforming. This is done by using an algorithm equivalent to the GCRA.

A return of the rate down to ICR is reflected in Algorithm B if the last CLP=0 backward RM-cell arrived at the source well before the return time to ICR (source behavior #5). In that case, the variable ICR_eligible is set equal to "TRUE" and only then can PACR be reduced down to ICR.

The following algorithm provides an approximate ABR conformance test:

```
Initialize:
 t_first = t_last = LVST = 0;
 tf = INFINITY;
 ICR eligible = FALSE;
 DER_first = DER_last = PACR = ICR;
 I_old = 1/ICR;
At each t_h(j) after a CLP=0 backward RM-cell departure with explicit rate
ER(i):
 ER(j) = min(PCR, max(MCR, ER(j)));
 IF ER(j) \ge DER_first
                            (* increase over first scheduled rate? *)
   THEN t_{last} = 0;
                                 (* un-schedule future decrease rate (if any))*)
           DER first = ER(i);
                                       (* update scheduled rate *)
           DER_last = ER(j);
           IF t_first < tb(j)
                                       (* no first rate scheduled? *)
                THEN t_h(j) + \tau 3; (* schedule new increase *)
           IF ER(j) \ge PACR
                 THEN t_first = min (t_first, t_h(j) + \tau 3);
                            (* reschedule if DER first was decrease *)
IF ER(j) < DER_first (* decrease over the current, first scheduled
                      increase? *)
   THEN t_last = t_h(j) + \tau 2
                                 (* schedule the time for the decrease *)
           DER_last = ER(j) (* schedule the decreased rate *)
           IF t_first < tb(j) (* first event has taken place? *)</pre>
                 THEN t_first = t_last;
                      DER_first = ER(j);
                                 (*schedule first event like second event *)
 IF t_h(j) + \tau 2 < tf + ADTF - \tau 1 (*cell arrives at source before a possible
                                       rate return down to ICR? *)
   THEN ICR_eligible = TRUE;
   ELSE ICR_eligible = FALSE;
When real time t reaches t_first:
 PACR = DER_first;
 t_first = t_last;
 DER_first = DER_last;
At arrival of a forward CLP=0 cell at time t_a(k):
```

```
IF cell k is a CLP=0 forward RM-cell  
THEN\ IF\ t_a\ (k)\ - tf > ADTF\ + \tau 1\ and\ ICR\_eligible=TRUE  
THEN\ PACR=min(PACR,\ ICR);  
tf=ta(k);  
ICR\_eligible=FALSE;  
I(k)=1/PACR  
I'=min(I(k),\ I\_old); \quad (*\ I'\ is\ an\ auxiliary\ increment\ variable\ *)  
IF\ LVST+I'\leq t\_now+\tau_1\quad (*\ cell\ conforming?\ *)  
THEN\ LVST=max\ (t_a(k),\ LVST+I');  
I\_old=I(k); \quad (*\ cell\ conforming,\ update\ parameters\ *)  
ELSE\ ; \qquad (*\ cell\ not\ conforming\ *)
```

III.4 Measures of ABR RM-Cell Conformance: Examples

The source behavior in Section 5.10.4 and destination behavior in Section 5.10.5 state explicit conditions under which forward and backward RM-cells shall be sent with CLP=0. From the perspective of a source, these conditions result in a specific ordering of forward and backward RM-cells relative to other cells on the connection. Switch behavior #3, however, allows RM-cells to be served out of sequence with respect to data cells at switches. As a result, a specific ordering of forward and backward RM-cells and other cells cannot be expected at network interfaces. Nevertheless, the relative numbers of each type of cell received at an interface over sufficiently long intervals should observe certain constraints. The section provides examples of such constraints.

Source Behavior #3 in Section 5.10.4 results in three distinct regions for the generation of CLP=0 forward RM-cells. In the first region, one forward RM-cell is sent for every Nrm CLP=0 cells on the connection and at least at a rate of one per interval Trm. In the second region, one forward RM-cell is sent per interval Trm. Finally, in the third region, one forward RM-cell is sent per Mrm+1 cells on the connection but at a rate no greater than one per interval Trm. As a result, over any interval of length L (in seconds), the number $R_{CLP=0}^f$ of CLP=0 forward RM-cells received on the forward connection at the public or private UNI or BICI and the total number $R_{CLP=0}^f$ of CLP=0 cells received on the forward connection at the interface should satisfy

$$c \times \frac{R_{CLP=0}}{Nrm} - d \le R_{CLP=0}^f \le \max \left(a, b \times \min \left(\frac{R_{CLP=0}}{Nrm} + \frac{L}{Trm}, \frac{R_{CLP=0}}{Mrm + 1} \right) \right)$$
 (C1)

where a, b, c, d, Nrm, Mrm, and Trm are constants common to all ABR connections at the interface. The units for a and d are cells and for Trm is seconds/cell. The constants b > 1 and c < 1, which describe the tolerance to deviations from ideal source behavior (as can occur if some cells are lost between the source and the interface in question) are dimensionless, as are Nrm and Mrm. The constants a and d account for deviations from ideal ratios that occur when a small total number of cells are received at the interface on the connection

Likewise, over any interval of length $L > \tau_2$, the number $R_{CLP=0}^b$ of CLP=0 backward RM-cells received at the interface on the connection, the number $T_{CLP=0}^f$ of CLP=0 forward RM-cells transmitted at the interface on the corresponding backward connection, and the number $T_{CLP=1}^f$ of CLP=1 forward RM-cells transmitted at the interface on the backward connection should satisfy

$$g \times \min(T_{CLP=0}^f, R_{CLP=0}^f) - h \le R_{CLP=0}^b \le \max(e, f \times (T_{CLP=0}^f + T_{CLP=1}^f + 10L(S+1))),$$
 (C2)

where S is the number of switches through which the received backward RM-cells pass between the source/destination and the interface in question, where e, f, g, and h are constants common to all ABR connection at the interface and where τ_2 is specified for the connection in question, as described earlier in Section 4.5.4. The constants e and h are in units of cells, and the constants f > 1 and g < 1, which describe the tolerance to deviations from the ideal source/destination behavior, are dimensionless.

An ABR connection that observes the reference behavior for an ABR source also should copy its most recently calculated Allowed Cell Rate (ACR) into the Current Cell Rate (CCR) field and its Minimum Cell Rate (MCR) into the MCR field of each forward RM-cell. When the forward RM-cell arrives at the private or public UNI or BICI, its CCR field should not exceed the inverse of the increment calculated by the algorithm $DGCRA(MCR^T,PCR^T,ICR^T,\tau_p,\tau_p,\tau_p)$ at that time, and its MCR field should not exceed the negotiated MCR for the connection. Hence, the number R_v^T of forward RM-cells received at the interface with CCR field more than the inverse of the calculated DGCRA increment or with MCR field greater than the negotiated MCR should satisfy

$$R_V^f \le \max\left(u, v \times \left(R_{CLP=0}^f + R_{CLP=1}^f\right)\right) \tag{C3}$$

over any interval, where $R_{CLP=1}^f$ is the number of CLP=1 forward RM-cells received on the forward connection over the interval and u and v are constants common to all ABR connections at the interface. The constant u is in units of cells, and the constant v is dimensionless. Condition (C3) assures that the ratio of the number R_v^f of forward RM-cells with CCR or MCR field in violation to the total number $R_{CLP=0}^f + R_{CLP=1}^f$ of forward RM-cells is close to 0, except when $R_{CLP=0}^f + R_{CLP=1}^f$ is small (i.e., $R_{CLP=0}^f + R_{CLP=1}^f < \text{u/v}$).

Informative Appendix IV: Application Examples for ATM Service Categories

This section identifies some example applications that are appropriate targets for each of the defined service categories. ITU-T Recommendation I.211 gives more examples and further details on some types of applications.

These example applications are provided to convey the original intention and focus of the service categories, which broadly relate application aspects to network functionality. However, an application is not constrained by this mapping, and may select any service category consistent with its needs. Example applications for CBR:

• Interactive Video (e.g., videoconferencing)

• Interactive Audio (e.g., telephone)

Video Distribution (e.g., television, distributed classroom)

Audio Distribution (e.g., radio, audio feed)
 Video Retrieval (e.g., video on demand)
 Audio Retrieval (e.g., audio library)

• Any data/text/image transfer application that contains smooth enough traffic or for which the end-system's response time requirements justify occupying a fully reserved CBR channel.

Example applications for real-time VBR:

- A real-time application (including those listed above for CBR) for which the end-system can benefit
 from statistical multiplexing by sending at a variable rate, and can tolerate or recover from a small
 but non-zero cell loss ratio.
- A real-time application (including those listed above for CBR) for which variable rate transmission allows more efficient use of network resources.

Example applications for non-real-time VBR:

- Response time critical transaction processing (e.g., airline reservations, banking transactions, process monitoring)
- Frame Relay interworking

Example applications for UBR:

- Interactive Text/Data/Image Transfer (e.g., banking transaction, credit card verification)
- Text/Data/Image Messaging (e.g., email, telex, fax)
- Text/Data/Image Distribution (e.g., news feed, weather sat. pictures)
 Text/Data/Image Retrieval (e.g., file transfer, library browsing)
 Aggregate LAN (e.g., LAN interconnection or emulation)
- Remote Terminal (e.g., telecommuting, telnet)

Example types of applications for ABR:

- Any UBR application listed above that can take advantage of the ABR flow-control protocol in order to achieve a low cell loss ratio.
- Critical data transfer (e.g., defense information).
- Super computer applications.
- Data communications applications requiring better delay behavior, such as remote procedure call, distributed file service (e.g., NFS), or computer process swap/paging.

Example applications for GFR:

- Frame Relay Interworking
- Any UBR application listed above that has data organized into frames that can be delineated at the ATM layer (e.g. AAL-5).

Informative Appendix V: VCC to VPC Multiplexing Effects and VPC Cell Conformance

This appendix discusses the appearance of cell clumping produced on a VPC when multiplexing VCCs into it. Annex B.3 and section 4.4.1 discusses cell clumping resulting from delays due to cell queuing and scheduling. However, with VCC to VPC multiplexing, no delay need take place to create the appearance of cell clumping on the VPC. The probability distribution of this apparent clumping is different than clumping produced by queues for non-aggregated connections. This appendix describes example scenarios producing the appearance of cell clumping on a VPC and some example considerations to achieve cell conformance for VPCs in the presence of such clumping.

Figure V-1 shows an example where two independent CBR VCCs with PCR=170 c/s (64 Kb/s) are multiplexed into a 128 Kb/s VPC on an OC-3. No cell delays have occurred; the cells of the two independent VCCs simply arrived in adjacent slots. To the 128 Kb/s CBR VPC, one of the cells appears jittered from its TAT by about 1038 cell slots or 3 ms. If one of the VCCs had a PCR=171 c/s and the other had PCR=170 c/s, then the arrivals of one VCC would slip in phase with respect to the other VCC until they periodically formed a clump with a probability of one.

The figure shows how two CBR streams can create the appearance of a "clump" or burst of two cells on the VBR stream. As more CBR channels are multiplexed, more jittered cells may give the appearance of a larger burst.

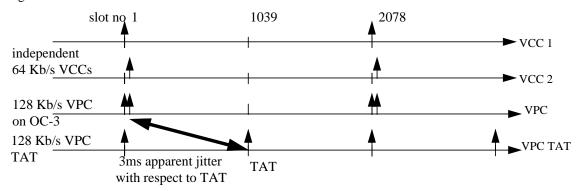

Figure V-1 Apparent VPC jitter produced by independent CBR VCCs

Figure V-2 shows a second example where two VBR VCCs with a SCR=170 c/s (64 Kb/s) are multiplexed into a 128 Kb/s VBR VPC. Each VCC has an MBS =32 and PCR = 353,208 c/s (150 Mb/s) on an OC-3. The frames consisting of 32 cells came from independent sources and the probability of overlapping in time at the VPC multiplexing point is not negligible.

The resulting VPC MBS appears twice as large, or 64 cells. If the MBS of the VPC is set at 32 cells, the last cell of the clump will be seen as non-conforming unless it is delayed to the VPC TAT, a delay of ~32,000 cell times or 0.1 seconds.

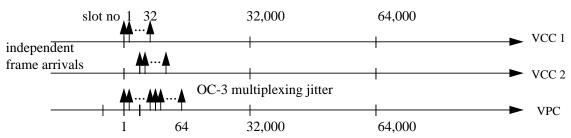

Figure V-2 Apparent MBS escalation produced by independent VBR VCCs

These two examples show two very simple cases of cell clumping created by multiplexing two VCCs into a VPC. This effect may be called "apparent jitter" to draw attention to the fact that the cells appear jittered

with respect to the VPC TAT, although no actual delay or jitter may have taken place. In general, the analysis of apparent jitter is complicated by factors such as:

- More than two VCCs
- VCCs of different characteristic MBS, PCR, SCR, MCR...
- VCCs of different service categories
- The VCC independence assumption may not hold
- Synchronous effects due to rolling cell arrival phase differences

There are no straightforward formulas to describe apparent jitter effects and none are offered here. Furthermore, there are no straightforward methods of insuring VCC QoS inside a VPC in the presence of these effects. It is up to the user of the document to account for these considerations.

The cells of a VPC containing many VCCs may be checked for conformance at some point in a network. To avoid adverse affects like cell losses at the VPC UPC function, one must insure a high probability of cell conformance. There are many methods to achieve cell conformance and the following examples do not preclude other methods.

One example method is to calculate the tail of the apparent jitter probability distribution and escalate the VPC UPC parameters to allow for the tail of the apparent jitter. Using this method, one must consider that the parameters escalated for some rare events at a tail of a probability distribution also allow traffic with similar parameters to pass UPC more frequently as well. For example, to engineer for a cell non-conformance probability of 10° for a VPC consisting of many low speed CBR VCCs, a burst of 15 back to back cell arrivals might have to be allowed by escalating CDVT. Even though a burst of 15 cells are expected with a low probability in this case (10°), UPC would find bursts of 15 cells across the interface conforming even if the cells always arrived in such a burst.

Another example method is to shape the VPC traffic to some parameters known to be able to contain the VCCs. The traffic shaper delays cells to insure cell conformance at the VPC. In so doing, it creates cell delays and jitter as seen by each contained VCC and by end applications. Low speed VCCs create larger delays. CBR VCC cell rates that differ only slightly from each other may create a rolling cell arrival phase difference producing a cell jitter alternating between VCCs rather than a constant delay on particular VCCs. Traffic shaping may be performed to a limited degree to prevent low speed timing sensitive applications from being affected by such jitter, especially if repeated traffic shaping takes place at multiple VPC multiplexing points in multiple networks.

The described methods of achieving VPC cell conformance are just two examples and do not preclude other methods. This text is offered as information to help the user of the document account for the apparent jitter effects due to VCC to VPC multiplexing.

Informative Appendix VI: Additional Information on the GFR Service

VI.1 Classification of Frames

Basic concepts

The set of frames belonging to a particular connection may be classified with regard to the basic concepts of

- 1. marking / tagging
- 2. frame conformance and
- 3. passing the F-GCRA(T,L)

The following figure is provided to visualize this classification and some derived concepts.

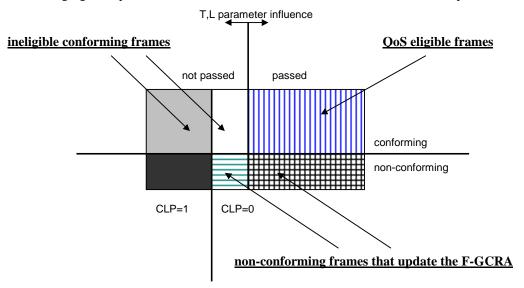

Figure VI-1 Classification of frames

Each of the basic concepts mentioned above partitions the set of frames as indicated by the annotations on both sides of the vertical and horizontal lines in figure VI-1.

Derived concepts

- The subset of OoS eligible frames is built by intersecting the passed and the conforming subsets.
- All cells in non-conforming frames whose first cell has CLP=0 are counted by the F-GCRA(T,L)
 algorithm. These frames count against the MCR, but being non-conforming the network is not obliged
 to deliver them.

VI.2 Simplified Frame Based Generic Cell Rate Algorithm: Simple-F-GCRA(T,L)

The algorithm specified in Annex B.5 is an ideal F-GCRA, which may be difficult to implement in real policers, shapers or schedulers.

This appendix provides a simplified algorithm that is equivalent to the F-GCRA(T,L) of Annex B.5 for connections containing only conforming frames. It may be used to implement policers, shapers or schedulers.

Part 1: Arrival of the first cell of a frame at time t_a at a given UNI or inter-network interface on the ATM connection:

```
X' := X - (ta- LPT)

if (X' > L) or (the cell has CLP=1) then
    passed := false
    else
        passed := true
endif

if (passed) then
        X := max(0, X') + T
        LPT := ta
endif
```

Part 2: Arrival of subsequent cells of a frame at time t_a at a given UNI or inter-network interface on the ATM connection:

In the above algorithm X denotes the value of the Leaky Bucket Counter and LPT is the Last Pass Time. X' and passed are auxiliary variables. At the time of arrival t_a of the first cell of the connection to cross the given interface, X = 0 and LPT = t_a .

VI.3 Discussion of the GFR Service Guarantee

VI.3.1 Introduction

This Appendix provides background material for those who wish to understand certain nuances of the GFR service guarantee. Understanding all this material is not necessary for most users of the GFR service category. Section VI.3.4 may be of general interest. Section VI.3.3 may be of particular interest to designers of GFR implementations. The discussion in Appendix VI.3 assumes all cells are conforming.

VI.3.2 An Unusual Phenomenon Unique to Frame-Based Services

The GFR service guarantee is to deliver, with high probability, a number of cells in complete unmarked frames at least equal to the number of cells in conforming frames that pass the F-GCRA(T,L) test of Annex B.5, with parameters T = 1/MCR and L = BT + CDVT.

Section VI.4 shows that the F-GCRA function may be implemented either implicitly or explicitly. Finite parameter granularities imply that an implementation, whether implicit or explicit, might not use exactly the T and L parameter values used to define the service guarantee. Intuition dictates that an implementation should use parameters that are no more constraining than T and L, i.e. an increment no larger than T and/or a tolerance at least as large as L. While any such implementation is valid for supporting GFR, an unexpected phenomenon can theoretically arise whereby fewer cells are given service than are eligible for the service guarantee. This phenomenon, which is considered to be sufficiently rare that it is not inconsistent with the above service guarantee, is explained in this section.

Suppose that T' and L' are chosen so that $T' \le T$ and $L'/T' \ge L/T$. For cell-based services, a network that services cells that conform to GCRA(T', L') will always service at least as many cells as a reference network that services cells that conform to GCRA(T, L). However, the analogous statement does not hold for frame-based services. For example, the number of cells that pass F-GCRA(T',L') is not guaranteed to be as large as the number that pass F-GCRA(T,L). This difference between cell-based and frame-based services occurs because frames can vary in size.

The use of some graphs and a specific example will help make this point clear. In the F-GCRA algorithm, the eligibility of a conforming CLP=0 frame is determined by the value of the state variable, X'. X' is a measure of how much guaranteed service has been granted in excess of the rate MCR. If, when the first cell of a frame arrives, X' is greater than L (which is related to MBS), then the burst in excess of MCR is considered to be so large that the service guarantee no longer applies. The evolution of X' in the algorithm F-GCRA(T, L) is illustrated in Figure VI-2. In this example, conforming CLP=0 cells arrive back-to-back at a rate PCR in frames 3 cells in length.

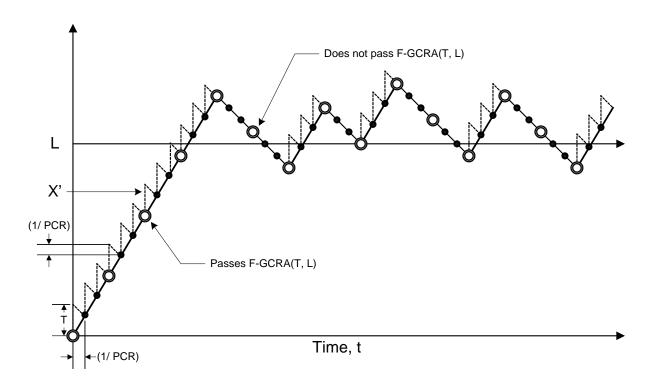

Figure VI-2 F-GCRA state variable as a function of time.

X' is only evaluated at the discrete points in time when cells arrive. When a cell arrives, X' is set to X' minus the amount of time elapsed since the last cell arrival, and then, if the cell is eligible, X is set to X' plus T = 1/MCR. In the plot, the dotted saw-tooth line connects the values of X' and X as time elapses and cells are processed. Open dots represent the time and value of X' at the arrival of the first cell of a frame; solid dots represent the time and value of X' at the arrival of subsequent cells of a frame. The peak of each saw-tooth represents the incremented value of X for each cell of a frame that passes the F-GCRA. In this example, the first 4 frames pass F-GCRA(T, L) and are eligible. Subsequently, 2 frames are ineligible, 1 frame is eligible, 1 frame is eligible, 2 frames are ineligible, and 1 frame is eligible.

This example illustrates the behavior of an F-GCRA when subjected to continuous demand at a rate higher than MCR. A burst of frames passes the F-GCRA, in this case a burst of size 4. Subsequently, frames pass the F-GCRA only at a rate consistent with MCR.

The dotted line illustrates X' and X being incremented by T and then dropping in accordance with the elapsed time until the next cell arrives. This level of detail may help one understand the nature of the diagram, but is not essential to tracking what frames pass and do not pass the F-GCRA. The solid line connects only the values of X' at each cell arrival. This smoother curve is sufficient for tracking the values of X' that determine whether frames pass the F-GCRA. This curve alone is used in the next plot.

Consider what happens when duplicate traffic is submitted to F-GCRA(T, L) and F-GCRA(T', L), where T' < T. Since T' corresponds to a larger minimum cell rate than does T, one expects that in general, F-GCRA(T', L) should pass more traffic than GCRA(T, L). Figure VI-3 shows an example where this expectation is violated.

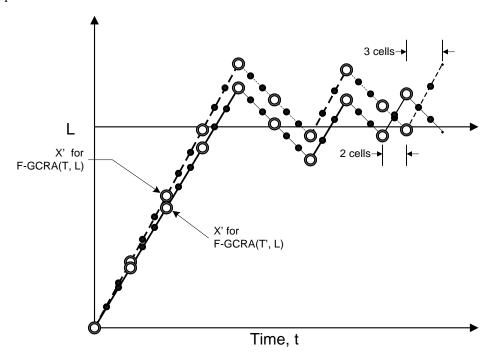

Figure VI-3 State variables of distinct F-GCRA instances.

The dashed line, which is initially higher corresponds to F-GCRA(T, L), while the solid line, which is initially lower corresponds to F-GCRA(T', L). A total of 29 cells burst at rate PCR. These are organized into 8 frames 3 cells long, a single frame 2 cells long, then another frame 3 cells long. F-GCRA(T', L), which is expected to pass the most traffic, passes frames 1-4, 7, and 9, and does not pass frames 5-6, 8, and 10, for a total of 17 cells passed. F-GCRA(T, L), which is expected to pass less traffic, passes frames 1-4, 7, and 10 and does not pass frames 5-6 and 8-9. It passes a total of 18 cells. Contrary to expectations, F-GCRA(T, L) passes more cells than F-GCRA(T', L) in this example. The reason this can happen is that any two F-GCRA algorithms with distinct parameters can eventually lose synchronization, and then will pass different frames. Because frames can have different sizes, for certain traffic patterns there can be counterintuitive results regarding which F-GCRA passes more cells.

This phenomenon does not occur if all frames have the same size.

VI.3.3 Implications of the Above Phenomenon for the GFR Service Guarantee

The phenomenon illustrated in the previous section is potentially problematic for the GFR service guarantee. Apparently, an F-GCRA implementation that uses parameters less constraining than T and L might service fewer cells than are eligible for the service guarantee. Such an implementation should intuitively be considered valid, yet the service guarantee appears not to be met.

Some observations about the phenomenon are in order. In this discussion we will call the F-GCRA(T',L) the "implemented F-GCRA" and the F-GCRA(T,L) the "service guarantee F-GCRA."

First, note that for most of the example in Figure VI-3 the implemented F-GCRA has serviced at least as many, and sometimes more cells than the service guarantee F-GCRA. It is only at the end point that the implemented F-GCRA seems to fall behind. Presumably, if the burst continued we would see the F-GCRA once again get ahead of the service guarantee F-GCRA, and if the burst continued long enough it would get

far enough ahead that it could never again fall behind. Indeed, in order to fall behind, it is necessary that the implemented F-GCRA first get ahead of the service guarantee F-GCRA.

Second, while it will be possible to reproduce the phenomenon in a testing environment, and while it will be expected that it will occasionally occur naturally in a real network, it will tend to be balanced by occasions when the implemented F-GCRA serves more cells than required. Considering the net number of cells served by an implemented F-GCRA compared to the number defined as eligible, there is no reason to expect that the occasions when the implemented F-GCRA falls behind will be other than rare.

Third, the GFR service guarantee is to serve a certain number of cells "with high probability," not with certainty. Furthermore, Section 3.2 of this specification states:

"QoS commitments ... are intended to be only a first order approximation of the performance that the network expects to offer over the duration of the connection. ... QoS commitments can only be evaluated over the long term and over multiple connections with similar QoS commitments."

For these reasons, the fact that this phenomenon will rarely occur is acknowledged, but is not considered to be inconsistent with the GFR service guarantee, and does not invalidate a GFR implementation.

An F-GCRA(T - ε , L + δ) implementation in which $\varepsilon \ge 0$ and $\delta \ge$ MFS will never experience the phenomenon shown in Section VI.3.2, i.e. the number of cells passing the F-GCRA will always be at least as large as the number passing F-GCRA(T, L). An implementation for which (L + δ)/(T - ε) - L/T \ge MFS also has this property. An implication of this is that it is possible to strictly fulfill the service guarantee if an implementation allocates bandwidth and/or buffer to the degree given by this relation.

In addition to the above observations, it is important to understand that these anomalous cases represent a subtle phenomenon that does not compromise the intuitive notion of what should be guaranteed. In particular:

- 1. The phenomenon never causes net throughput to drop below MCR. It occurs when the number of cells served recently exceeds the amount required by MCR by an amount on the order of (MBS 1)*(1 MCR/PCR). The phenomenon only decreases the excess relative to MCR.
- 2. The phenomenon does not cause bursts to lose service guarantee eligibility before they exceed MBS cells. For any allowed implementation, once MBS cells have been sent at PCR, additional frames can be serviced as long as the average cell rate drops to MCR or below. The phenomenon only affects detailed comparisons to the F-GCRA(T,L) behavior in this "after the burst" regime.

The phenomenon described in this section is not relevant to services that deal with cells but not frames, since cells are fixed-size data units.

VI.3.4 Using the Service Guarantee

While implementations of the GFR service may vary, the service guarantee has a number of properties that always hold. If all frames are conforming, then:

- 1. If a GFR connection has been idle and then sends a burst of cells, the GFR service guarantee ensures that every CLP=0 frame will be serviced, provided that the number of CLP=0 cells in the burst through the first cell of the last frame does not exceed MBS.
- 2. If CLP=0 frames are sent at a sufficiently high rate, then the average rate of the arriving cells that get serviced will be at least MCR.

There are subtleties to these statements. In the case of the first statement, there is the question of what it means to say that the "connection has been idle." For the purpose of this discussion, it is sufficient if the connection has not sent any CLP=0 cells for a period (BT+CDVT).

For the second statement to hold, it is not sufficient that the average rate at which CLP=0 cells are sent exceeds MCR. There must also not be excessively long gaps when nothing is sent. Consider an example. Let PCR = 10×MCR, and for simplicity assume frames are 1 cell long. Suppose a connection sends bursts of length 10×MBS alternating with gaps long enough to make the average cell rate MCR. The reference F-GCRA would consider the first MBS frames in a burst eligible for guaranteed service, plus every tenth frame thereafter. The mean rate of cells granted guaranteed service by the reference F-GCRA would be

0.19×MCR. So, because of gaps in the arriving traffic, the rate of cells granted guaranteed service would be far below MCR despite the average cell arrival rate being MCR.

VI.4 Example Designs and Implementations of the GFR Service

There are at least three mechanisms that can be used by the network to provide the per-connection minimum rate guarantees for GFR -- tagging, buffer management, and scheduling:

Tagging: Network based tagging can be used as a means of reducing priority of frames not eligible for the QoS guarantee before they enter the network. This form of tagging is usually performed when the connection enters the network. Network based tagging on a per-connection level requires some per-connection state information to be maintained by the network. Tagging can isolate QoS-eligible and non-QoS-eligible traffic of each connection so that other rate enforcing mechanisms can use this information to treat the QoS-eligible traffic preferentially over non-QoS-eligible traffic. For example, buffer thresholds can be used to discard tagged frames, thus allowing only QoS-eligible frames to enter the network at impending congestion.

Buffer management: Buffer management is typically performed by a network element (like a switch or a router) to control the number of frames entering its buffers. In a shared buffer environment, where multiple connections share common buffer space, per-connection buffer management can control the buffer occupancies of individual connections. Per-connection buffer management uses per-connection accounting to keep track of the buffer occupancies of each connection. Examples of per-connection buffer management schemes are Selective Drop and Fair Buffer Allocation. Per-connection accounting introduces overhead, but without per-connection accounting it is difficult to control the buffer occupancies of individual connections (unless non-conforming frames are dropped at the entrance to the network by the policer).

Scheduling: While tagging and buffer management control the entry of frames into a network element, queuing strategies determine how frames are scheduled onto the next hop. In a FIFO queue, frames are scheduled in the order in which they enter the buffer. As a result, FIFO queuing cannot isolate frames from various connections at the egress of the queue. Per-connection queuing, on the other hand, maintains a separate queue for each connection in the buffer. A scheduling mechanism can select between the queues at each scheduling time. However, scheduling adds the overhead of per-connection queuing and the service discipline.

The following subsections list some sample GFR implementations based on this framework. Section VI.4.1 presents an implementation that uses per-connection queuing with per-connection thresholds for CLP=0 cells, as well as support for treating CLP=1 cells separately from CLP=0 cells. Section VI.4.2 presents a sample implementation with FIFO queuing and two global thresholds, i.e., it is sensitive to CLP, but does not employ per-connection buffer management. Section VI.4.3 describes the Differential Fair Buffer Allocation Policy that uses FIFO queuing, per-connection thresholds and supports marking by the source or tagging by the network.

VI.4.1 GFR Implementation Using Weighted Fair Queuing and per-connection accounting

In this section we describe a sample implementation to support GFR using per-connection scheduling (Weighted Fair Queuing) and accounting. Many other similar implementations are possible, and this example is only provided for illustrative purposes.

This implementation serves an individual connection at a rate of at least MCR using a WFQ-like scheduler.

Buffer management is based on per-connection accounting that involves keeping the following variables for each flow i:

Q_i: Current number of CLP=0 cells stored for flow i

PS_i: Frame state bit (discard = 1)

The global constant QT is also required:

QT: Current total number of cells (CLP=0+1) stored for all flows

In addition, the following constants are also used:

- T_i : Buffer occupancy threshold for CLP=0 cells of flow i. This value should typically be the same as the above MBS value.
- LBO: Low buffer occupancy level. This triggers discarding of a CLP=1 frame. The exact value is implementation dependent.
- HBO: High buffer occupancy level. This triggers discarding of a CLP=0 frame. The exact value is implementation dependent.
- QMAX: Maximum buffer content.

Note that QMAX and HBO are assumed to be global for simplicity, but they could easily be chosen to be also flow specific.

The decision on whether to store a cell is made upon receipt of the first cell of the frame to which the cell belongs. When the first cell of a frame is received, this decision depends on a number of factors, such as whether the cell has CLP=1, the current buffer occupancy for its flow, and the current total buffer occupancy. The algorithm for this decision for the first cell of a frame from flow i is based on the pseudocode shown below.

```
IF (cell_has_CLP1) {
      IF (QT > LBO) {
            * The buffer occupancy is above low water mark
            discard_cell;
            set PS_i = 1; /*Ensure all subsequent cells are discarded*/
      } ELSE {
            * There is plenty of buffer space so even CLP=1
            * cells can be accepted
            * /
            accept_cell;
            PS_i = 0; /* Remembers first cell was accepted */
                        /* Increments total buffer content */
            OT++
      }
ELSE
      /* cell has CLP=0*/
      IF ((Q_i > T_i) \text{ and } (QT > HBO)) {
            * The flow already has more than its buffer share and
            * the total buffer occupancy is above high water mark
            * /
            discard_cell;
                        /*Ensures all subsequent cells are discarded */
            PS_i = 1;
      } ELSE IF (QT < QMAX) {
            * There is some buffer space left
            accept_cell;
            PS_i = 0;
                       /* Remembers first cell was accepted */
            Q_i++;
                     /*Increments counter of CLP=0 cells for flow i*/
            OT++;
      } ELSE {
            /*
            * No buffer space left
            * /
            discard cell;
            PS_i = 1; /* Ensures all subsequent cells are discarded */
```

```
}
}
```

The algorithm for determining whether to accept cells after the first cell in a frame is as follows:

```
IF ((PS_i=0) \text{ and } (QT < QMAX)) {
      /*
      * First cell was accepted and there is still
      * buffer space left
      accept_cell;
      IF (cell_has_CLP0) {
                    /* Update count of stored CLP=0 cells */
      QT++;
} ELSE {
      * Either first cell was not accepted or there is
      * no buffer space left
      discard_cell;
      PS_i = 1; /* Makes sure subsequent cells are discarded */
```

Note that when discarding the tail of a frame because one of its cells could not be accepted due to lack of buffer space, the end of frame notification should be preserved to avoid affecting the next frame. This can be achieved in a number of ways, but was left out of the pseudo code description to keep the description simple.

In addition to the above steps, each time a cell is transmitted, the following operation is performed:

```
IF ((cell_is_from_flow_i) and ( cell_has_CLP0)) {
       Q<sub>i</sub>--;
QT--;
```

This simply amounts to decrementing the buffered cell count for flow i.

As mentioned earlier, there are many possible variants of the GFR service that use different cell acceptance criteria based on buffer occupancy information. The pseudocode above represents just one implementation that will support the requirements of the GFR service.

VI.4.2 GFR Implementation Using Tagging and FIFO Queue

In this section we assume a FIFO server so that the service rate guarantee of GFR cannot be provided by the service discipline itself. Hence it is necessary to rely on a tagging function to identify those cells that are eligible to receive the service guarantee. As a result, this assumes that the F-GCRA algorithm described in Annex B.5 is used to determine which cells to tag. This tagging can be performed either at the network access point or at the switch element itself, if the capability to check for eligibility of cells from each flow is available.

Assuming that the tagging function has been performed according to the rule of Annex B.5, the acceptance of a new cell in the FIFO is as follows:⁴

The following global and per flow variables are maintained:

```
QT: Current total number of cells (CLP=0+1) stored in the FIFO.
```

 PS_i : Frame state bit for flow i ($PS_i = 1$ means discard CLP=1 cells)

In addition, the following constants are also used:

Note that we again distinguish between the first and subsequent cells in a frame.

LBO: Low buffer occupancy level. This triggers discarding of a CLP=1 frame. The exact value is implementation dependent.

HBO: High buffer occupancy level. This triggers discarding of a CLP=0 frame. The exact value is implementation dependent.

QMAX: Max buffer content (FIFO size).

Pseudocode for acceptance decision of first cell of a frame is shown below:

```
IF (cell_has_CLP1) {
      IF (QT > LBO) {
            * Buffer is above low water mark
            discard_cell;
                        /* Make sure subsequent cells are discarded */
            PS_i = 1;
      ÉLSE {
            * There is plenty of buffer space so even CLP=1
            * cells can be accepted
            accept_cell;
            PS_i = 0; /* Remembers first cell was accepted */
                        /* Increments total buffer content */
} ELSE {
      * cell has CLP=0
      IF (QT < HBO) {
            * Buffer content is below high water mark
            accept_cell;
            PS_i = 0; /* Remembers first cell was accepted */
                        /* Increments total buffer content */
            OT++;
      } ELSE {
            * No buffer space left
            discard_cell;
            PS<sub>i</sub> = 1; /* Ensures all subsequent cells are discarded */
      }
Acceptance for cells after the first one in a frame determined as follows:
IF ((PSi=0) \text{ and } (QT < QMAX)) {
      * First cell was accepted and there is
      * still buffer space left
      accept_cell;
                  /* Increments total buffer content */
      OT++;
} ELSE {
      * Either first cell was not accepted or there is
      * no buffer space left
      * /
      discard_cell;
      PS_i = 1; /* Makes sure subsequent cells are discarded */
}
```

Finally, each time a cell is transmitted out of the FIFO queue, the following update is performed: QT--; /* decrement total buffer content */

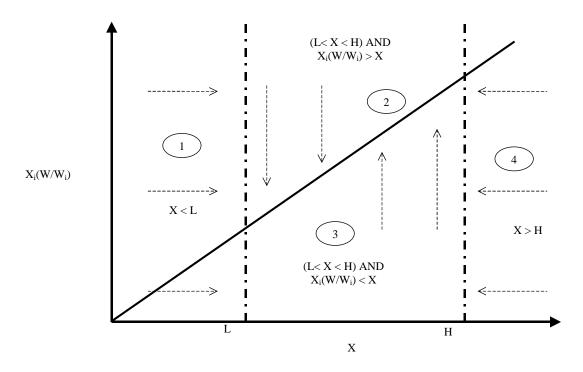

The above implementation is clearly simpler than the one described in Appendix VI.4.1, but this simplicity comes at some cost. In particular, fairness in the usage of excess bandwidth is essentially absent. However this implementation is still consistent with the requirements of the GFR service.

VI.4.3 GFR Implementation Using Differential Fair Buffer Allocation

Differential Fair Buffer Allocation (DFBA) uses the current queue length as an indicator of network load. The scheme tries to maintain an optimal load so that the network is efficiently utilized, yet not congested. In addition to efficient network utilization, DFBA is designed to allocate buffer capacity fairly amongst competing connections. This allocation is proportional to the MCRs of the respective connections. The following variables are used by DFBA to fairly allocate buffer space:

- X = Total buffer occupancy at any time
- L = Low buffer threshold
- H = High buffer threshold
- MCR_i = MCR guaranteed to connection_i
- W_i = Weight of connection_i = MCR_i/(GFR capacity)
- $\mathbf{W} = \mathbf{\Sigma} \mathbf{W}_{i}$
- X_i = Per-connection buffer occupancy $(X = \sum X_i)$
- $Z_i = Parameter (0 \le Z_i \le 1)$

DFBA tries to keep the total buffer occupancy (X) between L and H. When X falls below L, the scheme attempts to bring the system to efficient utilization by accepting all incoming frames. When X rises above H, the scheme tries to control congestion by performing EPD. When X is between L and H, DFBA attempts to allocate buffer space in proportional to the MCRs, as determined by the W_i for each connection. When X is between L and H, the scheme also drops low priority (CLP=1) frames so as to ensure proportional buffer occupancy for CLP=0 frames.

The figure above illustrates the four operating regions of DFBA. The graph shows a plot of the current buffer occupancy X versus the normalized fair buffer occupancy for connection i. If connection i has a weight W_i , then its target buffer occupancy should be X^*W_i/W . Thus, the normalized buffer occupancy of connection i is $X_i^*W_i/W_i$. The goal is to keep this normalized occupancy as close to X as possible, as indicated by the solid line in the graph. Region 1 is the underload region, in which the current buffer occupancy is less than the low threshold L. In this case, the scheme tries to improve efficiency. Region 2 is the region with mild congestion because X is above L. As a result, any incoming frames with CLP=1 are dropped. Region 2 also indicates that connection i has a larger buffer occupancy than its fair share (since $X_i > X^*W_i/W$). As a result, in this region, the scheme drops some incoming CLP=0 frames of connection i, as an indication to the connection that it is using more than its fair share. In region 3, there is mild congestion, but connection i's buffer occupancy is below its fair share. As a result, only CLP=1 frames of a connection are dropped when the connection is in region 3. Finally, region 4 indicates severe congestion, and EPD is performed here.

In region 2, the frames of connection i are dropped in a probabilistic manner. This drop behavior is controlled by the parameter Z_i , whose value depends on the connection characteristics. This is further discussed below

The probability for dropping CLP=0 frames from a connection when it is in region 2 depends on several factors. The drop probability has two main components – the fairness component, and the efficiency component. Thus, $P\{drop\} = fn(Fairness component, Efficiency component)$. The contribution of the fairness component increases as the connection's buffer occupancy X_i increases above its fair share. The drop probability is given by

$$P\{drop\} = Z_i \left(\alpha \frac{X_i - X \times W_i / W}{X(1 - W_i / W)} + (1 - \alpha) \frac{X - L}{H - L} \right)$$

The parameter α is used to assign appropriate weights to the fairness and efficiency components of the drop probability. Z_i allows the scaling of the complete probability function based on per-connection characteristics.

The following DFBA algorithm is executed when the first cell of a frame arrives at the buffer.

```
BEGIN
```

```
IF (X < L) THEN Accept frame  
ELSE IF (X > H) THEN  
Drop frame  
ELSE IF (L < X < H) AND (X<sub>i</sub> < X*W<sub>i</sub>/W)) THEN  
Drop CLP1 frame  
ELSE IF (L < X < H) AND (X<sub>i</sub> > X*W<sub>i</sub>/W)) THEN  
Drop CLP1 frame  
Drop CLP1 frame  
Drop CLP0 frame with  
P\{drop\} = Z_i \left( \alpha \frac{X_i - X \times W_i/W}{X(1 - W_i/W)} + (1 - \alpha) \frac{X - L}{H - L} \right)  
ENDIF
```

108

END

Informative Appendix VII: Measurement & Analysis of QoS Parameters

VII.1 Measurement Methods

In this section at least one method to measure each QoS parameter in either an in-service or out-of-service mode is defined. Other alternative measurement methods or estimates are possible.

Either in-service or out-of-service methods may be used to estimate values for the ATM cell transfer performance parameters. In-service methods are based on performance monitoring OAM flows that may be introduced into the user cell stream at any VPC or VCC termination or connecting point, and may then be copied or extracted at any similar point downstream. Details of OAM functions supporting performance measurement are provided in ITU-T Recommendation I.610. Out-of-service methods consist of establishing a test connection at an appropriate measurement point, introducing a cell stream of known content and timing at that point, and then observing the cell stream at a remote measurement point.

VII.1.1 Cell Error Parameters

VII.1.1.1 Cell Error Ratio

A method using test stream for out-of-service measurement is described in Annex C of ITU-T Recommendation I.356. It basically involves transferring a known data stream into the network at the source measurement point and comparing the received data stream with the known data stream at the destination measurement point.

An in-service measurement is desirable. Annex C of ITU-T Recommendation I.356 suggests a BIP-16 indicator to estimate the cell error ratio over a block of N cells.

VII.1.1.2 Severely Errored Cell Block Ratio

Severely errored cell block ratio can be estimated in service for a set of S consecutive or non-consecutive cell blocks by computing the number of lost cell or misinserted cell outcomes in each cell block, identifying cell blocks with more than M lost cell or misinserted cell outcomes as severely errored cell blocks, and dividing the total number of such severely errored cell blocks by S. This in-service measurement method will undercount severely errored cell blocks to some degree, since it does not include delivered errored cells in the estimation of M. A more accurate estimate of severely errored cell block ratio can be obtained by comparing transmitted and received data in an out-of-service measurement.

VII.1.2 Cell Loss Ratio

A method using OAM cells for in-service measurement is described in Annex C of ITU-T Recommendation I.356. The transmitter inserts OAM cells into a transmitted user information cell stream at suitable intervals. Each OAM cell contains a count of the number of user information cells transmitted since the last OAM cell. The receiver keeps a running count of the number of user information cells transmitted (N_t) and received (N_t). Cell loss ratio can then be calculated as (N_t - N_r) / N_t if N_t - N_r is positive. This method will under-count cell loss events if misinsertion occurs during the measurement period. It will over count loss if SECB events are not excluded.

VII.1.3 Cell Misinsertion Rate

A method using OAM cells for in-service measurement is described in Annex C of ITU-T Recommendation I.356. Counts, Nr and Nt, of the received and transmitted cells are obtained during a measurement period Tm (excluding cells in Severely Errored Cell Blocks), and the Cell Misinsertion Rate (CMR) is calculated by dividing the positive difference (Nr-Nt) by Tm. Cell misinsertion events will be under-counted if cell loss events occur.

An out-of-service measurement method is described in Annex C of ITU-T Recommendation I.356. Basically a VPC or VCC is maintained for a known period of time, however, no cells are transmitted on it. Any cells received on this VPC or VCC are misinserted cells.

VII.1.4 Cell Transfer Delay and Peak-to-Peak Cell Delay Variation

A method using OAM cells for in-service measurement is described in Annex C of ITU-T Recommendation I.356. Time stamped OAM cells are transmitted through the network on an established connection. The transmitted OAM cell payload contains the time stamp of the cell exit event. The receiver subtracts the received time stamp from the time stamp of the cell entry event to obtain the delay for that cell on that connection. Individual cell transfer delay observations may be combined to calculate statistics of the cell transfer delay distribution. This method requires synchronized clocks at the two measurement points, or a suitable reporting mechanism at the receiver, for example a loopback at the receiver.

Two statistics of the cell transfer delay distribution are currently defined in this specification. These are:

- 1. The maximum cell transfer delay, which is defined in Section 3.6.1.1 as the $(1-\alpha)$ quantile of CTD.
- 2. The peak-to-peak cell delay variation, which is defined in Section 3.6.1.2.3 as the difference between the $(1-\alpha)$ quantile of CTD and the fixed CTD that could be experienced by any delivered cell on a connection during the entire holding time.

Measurement estimates of the $(1-\alpha)$ quantile of CTD and the fixed CTD may be obtained from a sufficiently large number of CTD measurements. For the $(1-\alpha)$ quantile of CTD (or of any quantile of CTD) an unbiased estimate and associated confidence interval may be obtained. In general, for a desired statistical confidence, the number of measurements required increases as the quantile approaches 1. Note that an unbiased estimate of the absolute minimum CTD (i.e., the fixed CTD) cannot be obtained from a finite number of measurements. Rather, one can obtain an unbiased estimate of a lower quantile. In general, for a desired statistical confidence, the number of measurements required increases as the lower quantile approaches 0. The estimate may be used as a biased estimate of the fixed CTD. This estimate may be made arbitrarily close to the fixed CTD (in the statistical sense) using a sufficiently large number of measurements.

VII.1.5 Measuring Cell Non-Conformance Ratio

For the case of a connection described only by PCR and for a single cell flow (such as the aggregate CLP=0+1 cell flow), consider negotiated values for peak emission interval T and CDVT τ . Consider the variables c_k and y_k , which are defined as follows:

$$c_0 = a_0$$

$$c_{k+1} = \begin{cases} c_k & \text{if } c_k > a_k + \tau \\ a_k + T & \text{if } c_k \le a_k \\ c_k + T & \text{otherwise} \end{cases}$$

$$y_k = c_k - a_k$$

where a_k is the observed arrival time of cell k at the measurement point. Figure B-1 of ITU-T Recommendation I.356 illustrates a measurement method that calculates, for a cell stream received at a measurement point, the number of cells that do not comply with a specified peak emission interval and a CDVT. The virtual scheduling algorithm and continuous-state leaky bucket described in Section 4.4.2 as equivalent versions of the GCRA may be used to measure the cell non-conformance ratio. The mapping between the variables of the two equivalent algorithms are summarized in table B-1 of ITU-T Recommendation I.356.

VII.1.6 Measuring of Range of Cell Transfer Delay

Buffering procedures to implement AAL1 at the receiving side to compensate for cell delay variation are based on the expected maximum range of cell transfer delay. The actual range of cell transfer delay observed in a set of consecutive cells may be measured using the one-point CDV parameter y_k , which is defined in ITU-T Recommendation I.356. This parameter describes the variability in the pattern of cell arrival events at a MP with reference to the negotiated peak emission interval T. The one-point CDV y_k for cell k at a MP is the difference between the cell's reference arrival time c_k and the actual arrival time $a_k : y_k = c_k - a_k$. The reference arrival pattern is defined as follows:

$$c_0 = a_0$$

$$c_{k+1} = \begin{cases} a_k + T & \text{if } c_k \le a_k \\ c_k + T & \text{otherwise} \end{cases}$$

A positive value for y_k corresponds to a cell that experienced a smaller delay than the maximum delay experienced up to cell (k-1). A negative value for y_k corresponds to a cell that experienced the largest delay experienced by cells up to cell k. Figure VII-1 provides a method of estimating the range of cell transfer delay for a succession of transferred cells. This method assumes that cells are input uniformly at the PCR.

VII.2 Factors Affecting ATM QoS Parameters

This section provides a list of items to be considered in setting QoS parameter objectives dependent upon characteristics that can exist in either private or public networks, or combinations thereof as indicated in Figure 3-1. The objective is to have maximum commonality between public and private networks.

This section summarizes the set of ATM cell transfer performance parameters defined in ITU-T Recommendation I.356. The cell events and cell transfer outcomes defined in Section 3.4 of this document are used in defining these performance parameters. This set of ATM cell transfer performance parameters correspond to the generic criteria of the assessment (shown in parentheses) of the QoS (see ITU-T Recommendation I.356), as follows:

Cell Error Ratio (Accuracy)
Severely-Errored Cell Block Ratio (Accuracy)
Cell Loss Ratio (Dependability)
Cell Misinsertion Rate (Accuracy)
Cell Transfer Delay (mean and max) (Speed)
Cell Delay Variation (Speed)

VII.2.1 Sources of QoS Degradation

VII.2.1.1 Propagation Delay

This is the delay caused by the Physical media that transport the bits comprising ATM cells between UNIs and between ATM switches. This equally impacts public and private networks, dependent upon distance only. Private networks may extend from the desktop to international distances, while public networks generally extend from metropolitan to international distances.

VII.2.1.2 Media Error Statistics Delay

These are the random and/or bursty bit errors that are introduced on the physical media.

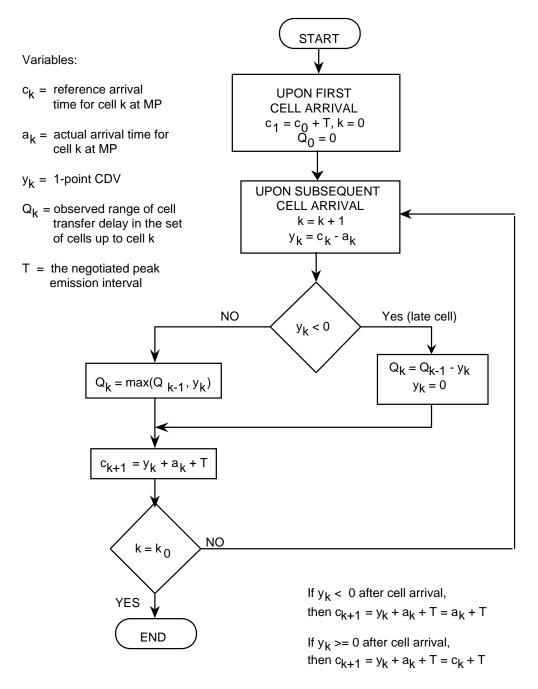

Figure VII-1: Estimation of the range of two-point CDV from one-point CDV for connections providing CBR service

VII.2.1.3 Switch Architecture Delay

The overall architecture of the switch can have significant impacts on performance. Some aspects to consider are the switch matrix design, buffering strategy and the switch characteristics under load. The switch matrix design may range from blocking to non-blocking. The strategy in which the buffer capacity of a port supporting the UNI on an ATM switch is managed may differ significantly across switch architectures. The buffer capacity may be dedicated to a single port, it may be shared between multiple ports, or some combination thereof. The management of this buffer capacity may range from a single First In First Out (FIFO) queue to a more complex, multiple queue system with an algorithmically defined service rule, that could operate based upon priorities. The switch matrix design may introduce some loss under heavy load conditions.

VII.2.1.4 Buffer Capacity Delay

This is the actual capacity of the buffer in units of cells at a port supporting the UNI, within an ATM matrix, or in other elements of an ATM switch.

VII.2.1.5 Traffic Load

This is the load offered by the set of ATM connections on the same route as the connection under consideration.

VII.2.1.6 Number of Nodes in Tandem

This is the number of ATM switching nodes that a particular connection traverses.

VII.2.1.7 Resource Allocation

This is the capacity allocated to a connection or to a set of connections, such as the set of connections on a given route that are assigned a given QoS class.

VII.2.1.8 Failures

These are events that impact availability, such as port failures, switch failures or link failures. Switch-overs between failing equipment or circuits may introduce cell loss.

VII.2.2 Impact of QoS Degradation on Performance Parameters

In this section the impact of each of the sources of QoS degradation on each of the Performance Parameters of Section 3 is analyzed in a subjective manner as a guideline for what degradations and factors should be considered in determining a value for the performance parameter. Note that the scope of QoS is from UNI to UNI as defined in Section 3.

VII.2.2.1 Cell Error Ratio and Severely Errored Cell Block Ratio

The cell error ratio is expected to be primarily influenced by the error characteristics of the physical media. The severely errored cell block ratio is also expected to be influenced by the error characteristics of the physical media and by buffer overflows.

Error characteristics may also be a function of the physical distance and the characteristics of the media. Operational effects such as transmission protection switching and rearrangements may also introduce errors.

VII.2.2.2 Cell Loss Ratio

The Cell Loss Ratio is expected to be influenced by errors in the cell header, buffer overflows, and the non-ideal UPC actions. Loss due to the noncompliance of a connection should be excluded when network caused losses are to be estimated.

Errors detected in the cell header at the physical layer affect the Cell Loss Ratio. Cells may also be lost due to failures, protection switching and path reconfiguration.

Different buffering and resource allocation strategies may cause buffer overflow characteristics to differ.

Queuing implementations in some networks may not provide large buffers, or multiple levels of priority since transmission capacity and resources will be relatively inexpensive. Therefore, cell loss ratios may be higher than in a more complicated network. A lost higher level PDU can be detected in a much shorter period of time in a local area than in a wide area, so that higher layer protocol re-transmissions can be initiated sooner and thus will have less impact on higher layer application throughput in local area networks than in wide area networks.

Buffering strategies in wider area or lower speed networks may be much more complex than that in local, high speed networks. Transmission capacity resources will be relatively more expensive. Multiple levels of delay priority, and possibly relatively large buffers, may be implemented. Within a delay-priority level the CLP bit may also be used to indicate two levels of loss priority. High delay-priority levels will likely have low loss ratios, while lower delay-priority levels may have higher loss ratios during periods of buffer congestion.

The number of nodes in tandem may also impact the CLR due to the possibility of overflow in any buffer between the source and destination.

Path reconfiguration from a long to a shorter route is also a possible cause of cell losses, due to the difference in propagation delay. Path reconfiguration is a process at the physical layer used when a path needs to be taken out-of-service to perform maintenance. A possible cause is as follows, after a new path is set up, traffic is transmitted on both paths until it can be verified (at the physical layer) that the new path is operating properly. At this time, a physical layer switch is made at the receiving end of the path. This process is intended to minimize the interruption to the customer service.

VII.2.2.3 Cell Misinsertion Rate

The cell misinsertion rate is expected to be primarily influenced by undetected/miscorrected errors in the cell header, which in turn is primarily influenced by the transmission error rate. The likelihood that an undetected/miscorrected cell header error maps into a valid VPI/VCI is also dependent upon the number of VPI/VCI values that are assigned and being actively used.

The cell error ratio will be dependent upon the factors defined in Section VII.2.2.1. The number of active ATM sources is likely to be less for a private network than for a public network. This should decrease the likelihood of an undetected/miscorrected cell header error resulting in a cell that is incorrectly misinserted into some other VPI/VCI cell stream at the destination UNI.

The number of sources that can be mapped into another cell address will likely be much larger in a public network than in a private network.

VII.2.2.4 Cell Transfer Delay

Cell transfer delay is affected by propagation, queuing, routing and switching delays, which are likely to differ for local and wide-area networks.

VII.2.2.5 Cell Delay Variation (CDV)

Specification of CDV is essential for Constant Bit Rate (CBR) connection performance. Its value is necessary for the dimensioning of the elastic buffer required at the terminating end of the connection for absorbing the accumulated CDV, regardless of whether the network is public or private.

A common, maximum cell delay variation value for private, public and hybrid private/public networks is essential. As an implementation guideline the receiver CDVT should be designed to handle the case where a connection traverses three networks, each having three switches in tandem.

VII.2.2.6 Degradation of QoS Parameters Summary

Table VII-1 summarizes how various sources of degradation can impact the QoS parameters.

Attribute	CER	SECBR	CLR	CMR	CTD	CDV
Propagation Delay					X	
Media Error Statistics	X	X	X	X		
Switch Architecture			X		X	X
Buffer Capacity		X	X		X	X
Number of Tandem Nodes	X	X	X	X	X	X
Traffic Load			X	X	X	X
Failures	X	X	X			
Resource Allocation			X		X	X

Table VII-1: Degradation of QoS Parameters

CER = Cell Error Ratio

SECBR = Severely Errored Cell Block Ratio

CLR = Cell Loss Ratio

CMR = Cell Misinsertion Rate

CTD = Cell Transfer Delay

CDV = Cell Delay Variation

VII.3 QoS Classes

A user of an ATM connection (a VCC or a VPC) is provided with one of a number of Quality of Service (QoS) classes supported by the network. It should be noted that a VPC may carry virtual channel links of various QoS classes. The QoS of the VPC must meet the most demanding QoS of the virtual channel links carried as defined in ITU-T Recommendation I.150. The QoS class associated with a given ATM connection is indicated to the network at the time of connection establishment and will not change for the duration of that ATM connection.

A QoS class can have specified performance parameters (Specified QoS class) or no specified performance parameters (Unspecified QoS class). QoS classes are inherently associated with a connection. A specified QoS class enumerates a set of performance parameters and specifies an objective value for each of these parameters. Examples of performance parameters that could be in a QoS class include: cell transfer delay, cell delay variation, and cell loss ratio, as currently defined in ITU-T Recommendation I.356.

It is possible to define two cell loss ratio parameters: CLR_{0-1} , which applies to the aggregate cell stream, and CLR_0 , which applies to the high priority cells, i.e., those with CLP=0. It is expected that other performance parameters besides the cell loss ratio would apply to the aggregate cell flow of the ATM connection. A QoS class could contain, for example, the following performance parameters: maximum/mean cell transfer delay for the aggregate flow⁵, cell delay variation for the aggregate flow, and cell loss ratio for the aggregate flow.

The network may support several QoS classes. At most one (1) unspecified QoS class can be supported. The performance provided by the network should meet (or exceed) performance parameter objectives of the QoS class requested by the ATM end-point. ATM connections shall indicate the requested QoS by a particular class specification. For PVC's the management system can be used by the network to report the QoS classes across the UNI. For SVCs, a signaling protocol's information elements can be used to communicate the QoS class across the UNI.

VII.3.1 Specified OoS Classes

A specified QoS class provides a quality of service to an ATM connection in terms of a subset of the ATM performance parameters defined in Appendix VII.2. Initial QoS classes for ATM connections over public networks are defined in ITU-T Recommendation I.356 (Section 8, Table 2/I.356). It is important to emphasize that the QoS classes defined in I.356 apply only to public networks, as opposed to private networks. I.356 considers a private network to be part of customer equipment / customer networks. In the case where a user is connected to a public network through a private network, the private network should qualitatively interpret the user-specified QoS class in a manner consistent with the user's expectations. In particular, this means that:

- 1. the choice of QoS class 1 by the user indicates that the user desires bounds on the delay parameters and a cell loss ratio commitment on the aggregate cell stream,
- 2. the choice of QoS class 2 by the user indicates that the user desires a cell loss ratio commitment on the aggregate cell stream, and
- 3. the choice of QoS class 3 by the user indicates that the user desires a cell loss ratio commitment on the CLP=0 cell stream.

The quantitative impact of private networks on the end-to-end QoS is an issue for further study in I.356 (version of October 1996), and is not currently addressed in I.356.

The ATM Forum has defined six service categories in Section 2. These are CBR, rt-VBR, nrt-VBR, UBR, ABR and GFR. A plausible association of the ATM Forum Service Categories with the ITU-T QoS classes

_

The relation between mean CTD as defined in I.356 and maximum CTD as defined in this specification is for further study.

can be deduced from the definitions. This plausible association is shown in Table VII-2 below. Note that this table does not mandate the use of any particular QoS class in any particular context.

Since ITU-T has discontinued Recommendation I.362 and the former service classes A, B, C and D that were defined in I.362, the previous association of QoS class with the former service classes is no longer applicable.

Table VII-2: Plausible Association of ATM Forum Service Categories and ITU QoS Classes.

Categories and 110 Qub classes.				
ATM Forum Service Category	ITU QoS Class			
(conformance definition)				
CBR (CBR.1)	1			
rt-VBR (VBR.1)	1			
rt-VBR (VBR.2)	See Note 1			
rt-VBR (VBR.3)	See Note 1			
nrt-VBR (VBR.1)	2			
nrt-VBR (VBR.2)	3			
nrt-VBR (VBR.3)	3			
ABR	3, U			
UBR (UBR.1, UBR.2)	U			
GFR (GFR.1, GFR.2)	3, U			

Note 1: ITU-T Study Group 13, Q14 has provisionally agreed at the June 1998 Study Group13/Q14 meeting to include a new Stringent Bi-Level QoS Class in the next published version of Recommendation I.356. This is the appropriate QoS class to associate with rt-VBR (VBR.2 and VBR.3)

VII.3.2 Unspecified QoS Classes

In the Unspecified QoS class, no objective is specified for the performance parameters. However, the network may determine a set of internal objectives for the performance parameters. In fact, these internal performance parameter objectives need not be constant during the duration of a call. Thus, for the Unspecified QoS class there is no explicitly specified QoS commitment on either the CLP=0 or the CLP=1 cell flow. Services using the Unspecified QoS class may have explicitly specified traffic parameters.

An example application of the Unspecified QoS class is the support of "best effort" service (i.e., UBR). For this type of service, the user selects the Best-Effort Capability, the Unspecified QoS class, and only the traffic parameter for the PCR on CLP=0+1. This capability can be used to support users that are capable of regulating the traffic flow into the network and to adapt to time-variable available resources.

The Unspecified QoS class is identified by the integer zero (0) in the ILMI MIB or a code point in a signaling message for the requested QoS class.

Informative Appendix VIII: Generic Negotiating Behavior

This informative appendix describes how signaling negotiates traffic contract and QoS parameters. Requirements on ABR control parameters are different, and are described in Section 5.10.2.1. It is intended to provide an overview of the negotiation process for the user of this specification, and only generic behaviors are provided. Specific procedures and encodings are provided in the UNI signaling and PNNI signaling specifications; the BICI 2.0 specification does not include negotiation, which is planned to be included in future versions.

VIII.1 Overview of Generic Negotiating Behavior

The purpose of the negotiation is to select a value of each parameter that can both be provided by the network and meets the needs of both end-systems. Since call establishment is accomplished in one round trip (two relevant messages), negotiation must be tied to a single round trip exchange. At the highest level, the calling end-system proposes a requested value and an acceptable value. The network tries to meet the requested value, or at least some value between the requested and acceptable value, and if it can't meet the acceptable value, it clears the call. Otherwise, it offers the call to the called end-system with the better of the requested value and the best value it can support. In some cases, the signaling protocol does not explicitly support signaling for a desired value.

VIII.2 Details of Generic Negotiating Behavior

The protocol specifies a range of values for the parameter. Typically, the range is integer valued (although real or enumerated types are possible). In some cases, the range may be a choice of two (or more) discrete values. One end of the range is designated as the "most desirable" value, and the other is the "least desirable" value. If the most desirable value is greater than the least desirable, the negotiation proceeds downwards, i.e., decreases in value. Otherwise, negotiation is upwards, i.e., increases in value. For example, a high cell rate is considered more desirable than a lower one, and negotiation proceeds downwards, while a low CTD is more desirable than a higher one, so CTD negotiation proceeds upwards.

The protocol also determines whether the objective of the negotiation is to "meet" or to "meet or exceed" the parameter value indicated by the calling end-system. If the objective is to meet the value, it is usually because the parameter relates to a resource (e.g., bandwidth) that can be divided with relatively fine granularity among calls, with a penalty to the network attached to giving a greater value to the connection than that indicated. If the objective is to meet or exceed, the network may have alternative values available not necessarily over a continuous range, and can't benefit from giving the connection exactly the value indicated rather than the next most desirable value. For example, peak cell rate is a "meet" parameter, since it can be divided fairly precisely among connections; if there is 10 Mb/s of capacity available, and the connection needs 3 Mb/s, then that quantity will be assigned (ignoring for the present imprecision and "fudge factors" present in real implementations), and the remainder will be available for other connections. Delay is a "meet or exceed" parameter; if a connection needs 50 ms, and routes are available that offer 20, 40 and 60 ms, respectively, then the 20 ms or the 40 ms route will be selected (all other things being equal), and there will be no reason to pad the delay out to 50 ms.

A parameter is characterized as either a "metric" or an "attribute". A metric is a parameter that requires the contribution of each topological component (i.e., link or node) to be accumulated to determine the value of the parameter for the connection. An attribute considers each topological component individually, such that the least desirable contribution of one or more links constitutes the parameter value for the connection. For example, delay is a metric, while peak cell rate is an attribute. In general, path calculation is facilitated by minimizing the number of metrics that can apply to the connection. Note that these definitions are consistent with, but not identical to, those in the PNNI specification.

Behavior
Direction
Meet/Meet or Exceed
Attribute or Metric
Accumulation Algorithm

Called end-system may select le	ess
desirable value	

CLR	maxCTD	CDV	
Up (Note 1)	Up	Up	
Meet/Exceed	Meet/Exceed	Meet/Exceed	
Attribute	Metric	Metric	
N/A	see Section 3.6.2	see Section	
		3.6.2	
no	no	no	

Note 1: The negotiation refers to the actual value of the parameter, and not to its encoding. For example, if $CLR = 10^x$, the value of the CLR parameter may be represented as x. Therefore negotiating the CLR upwards implies that the actual value of x decreases

Table VIII-1: Application of generic negotiating procedures to OoS parameters

VIII.3 Description of Generic Negotiation Algorithm

This section provides a high level description of the procedures for generic negotiation. Specific, detailed procedures and message formats are described in the signaling and PNNI specifications. These procedures are not supported in BICI 2.0, but are expected to be in future versions of the BICI specification.

The negotiation for each parameter operates as follows:

- 1. In the initial call establishment message, the calling end-system may indicates a "requested" value, which is the value of the parameter that it would like to have, and also indicates either a "highest acceptable value" (for upward negotiation) or a "lowest acceptable value" (for downward negotiation). The latter value is, respectively, the highest or lowest value of the parameter that the calling end-system is willing to accept; that is, it would rather the call be rejected than to have it completed with a higher or lower value, respectively. If the requested value is not specified (either because the calling end system chooses not to include it, or because it is not supported in the signaling protocol), it is assumed to be the same as the highest or lowest acceptable value.
- 2. The switch serving the calling end-system makes a preliminary determination as to whether it can meet the requested, or at least the highest or lowest acceptable value for the parameter. This might, for example, involve 'sanity checking', tests against administrative limits or path computation. If the network cannot satisfy at least the highest or lowest acceptable value, it rejects the call. These determinations may also be made at administrative boundaries between networks (e.g., at BICI interfaces, interfaces between public and private networks or PNNI border nodes).
- 3. If the parameter is an attribute, the network node interface carries an "indicated" value of the parameter, in addition to the requested and lowest or highest acceptable value. If the parameter is a metric, the network node interface carries a "cumulative" value of the parameter, in addition to the requested and lowest or highest acceptable value. The accumulation function is part of the specific negotiating behavior for the parameter, and also applies to path computation.
- 4. Each successive switching system determines an outgoing link over which it will progress the call, and determines the value of each parameter that applies to that link. For "meet" parameters, it selects the appropriate value for the parameter. For 'meet or exceed' parameters, it might or might not have a choice among several values, and if so, it selects one according to implementation specific criteria.
 - a) If the parameter is an attribute, the value of the parameter that applies to the outgoing link is compared with the lowest or highest acceptable value in the initial call establishment message.
 - If it is less desirable than highest or lowest acceptable value (i.e., higher than the highest acceptable value or lower than the lowest acceptable value, whichever applies), the call is cleared (or crankback occurs).
 - ii. If it is less desirable than the indicated value carried in the incoming initial call establishment message received from a preceding switching system, or if the initial call establishment message was received from an end-system, then the indicated value carried in the outgoing initial call establishment is set to the value that applies to the outgoing link.

- b) If the parameter is a metric, the accumulation function is applied to value of the parameter that applies to the outgoing link and the cumulative parameter value in the incoming initial call establishment message, resulting in the new cumulative value. If the new cumulative value is less desirable than highest or lowest acceptable value (whichever applies), the call is rejected (or crankback occurs). The new cumulative value is carried in the outgoing initial call establishment message.
- c) The call is progressed to the next switching system or the called end-system.
- 5. When the initial call establishment message is received at the called end-system, it contains the requested, either highest or lowest acceptable, and either indicated or cumulative values of the parameter. The called end-system determines whether or not the value is acceptable, and either accepts or rejects the call. For some negotiations (e.g., PCR), where the parameter value affects resources in the called end-system, called end-system may select a less desirable value for the parameter, as long as it is not less desirable than the highest or lowest acceptable value. In this case, the call connected message sent by the called end-system contains the agreed value, which is always between the indicated or cumulative value and the highest or lowest acceptable value contained in the received initial call establishment message.
- 6. The call connected message progressed through the network, and the call connected message sent to the calling end-system contains the agreed value, which applies for the duration of the call (absent protocol specifications for renegotiation).

END OF DOCUMENT
